The perpendicular distance from the vertex of the cone to its base is the altitude and the straight line from vertex to base is the axis. If the axis is perpendicular to the base, the solid is a right cone; otherwise, it is oblique. A circular cone has a circle for a base. If, in addition, it is a right cone, it is called a right circular cone and also a cone of revolution, for it may be produced by revolving a right triangle about one of its legs as an axis. The hypotenuse of the triangle in any position is the slant height of the cone.

A plane that cuts all elements of a cone divides the solid into two parts: another cone and a truncated cone. If the cutting plane is also parallel to the base, the resulting solid is called the frustrum of a cone. It has both a lower and an upper base; its altitude, lateral surface, and slant height are defined as for a cone.

The following relations hold for a cone of revolution: $S = sC/2 = \pi Rs$; $A = \pi R(R + s)$; $V = \pi R^2 h/3$ and, for the frustrum of such a cone: $S = s(C + c)/2$; $V = \pi h(R^2 + Rr + r^2)/3$. In these equations S is lateral areas; V, volume; A, total area; s, slant height; h, altitude; r, R and c, C radius and circumference of upper and lower base, respectively.

The volume of any cone is given by $V = Bh/3$ and the volume of any frustrum by $V = h(B + \sqrt{Bb} + b)/3$, where b, B refer to the areas of upper and lower bases.

See also **Conical Surface**; and **Conic Section**.

CONE-IN-CONE STRUCTURE. A concretionary structure frequently observed in limestone, dolomites, and other sedimentary rocks that originated as fine-grained sediments. As the term suggests the structure is formed by a series of concentric cones, the result of radial crystallization around a common axis, probably due to differential pressures.

CONFIDENCE INTERVAL. If a parameter θ of a frequency or probability distribution is estimated by a statistic t, the value of t calculated from any given sample will deviate from the value of θ. It is, however, often possible to set limits round t (dependent on the sample values) between which the value of θ may be asserted to lie with assigned probability. The range between these limits is a confidence interval. Customary probability levels for the purpose are 95% and 99%; for example, with 10 observations from a normal (Gaussian) distribution, if the sample mean is m and the sample standard deviation, calculated as $\sum^n (x - \overline{x})^2/(n-1)$, is s, the true mean may be asserted to lie in the interval $m \pm 2.23s$ with confidence 95%, meaning that if we always make such an assertion in such cases we shall be right 95 times in 100.

CONFIDENCE LEVEL. In statistics, the degree of desired trust or assurance in a given result. A confidence level is always associated with some assertion and measures the probability that a given assertion is true. For example, it could be the probability that a particular characteristic will fall within specified limits, i.e., the chance that the true value of P lies between $P = a$ and $P = b$. See also **Confidence Interval**.

CONFLUENT. A term used by geologists and physiographers to designate a stream that unites with another; especially applied to streams nearly equal in size.

CONFORMAL MAP (or Isogonal Map; Orthomorphic Map). A map that preserves angles, i.e., if two curves intersect at a given angle, the images of the two curves on the map also intersect at the same angle. On such a map, at each point, the scale is the same in every direction. Shapes of small regions are preserved, but areas are only approximately preserved (the property of area conservation is peculiar to the equal-area map).

The most commonly used conformal map is probably the Lambert projection, with standard latitudes at 30° and 60°N. On the standard latitudes, the scale is exact; between them, it is decreased by not more than about 1%; outside them, distortion increases rapidly. The Mercator and stereographic projections are also conformal maps.

CONFORMAL REPRESENTATION. Consider the real variables x, y, u, v and suppose $w = u + iv$ is a single-valued function of the complex variable $z = x + iy$. Now plot z and w in two coordinate planes: the z-plane, with x, y as axes and the w-plane, with u, v as axes. Wherever w is analytic, each point in the z-plane is related to a point in the w-plane and one says that the z-plane is mapped onto the w-plane by the transformation $w(z)$. Any infinitesimal figure in the w-plane becomes a similar figure in the z-plane with angles and proportions preserved. This is the reason for the terms conformal representation or mapping. Changes of size, called magnification, and displacement of figures frequently occur in such mappings.

As a simple example, consider $w = z^2$ and apply it to the area shown in Fig. 1. Polar coordinates are useful for we see that $z = re^{i\theta}$, $w = r^2 e^{2i\theta}$, the modulus of w equals r^2 and its amplitude is 2θ. The two arcs in the z-plane become semicircles of radii a^2, b^2 in the w-plane; the straight lines on the X, Y-axes remain straight lines but they are now on the U-axis. The transformation is conformal everywhere within and on the boundary of the curves but the magnification is $2|z|$.

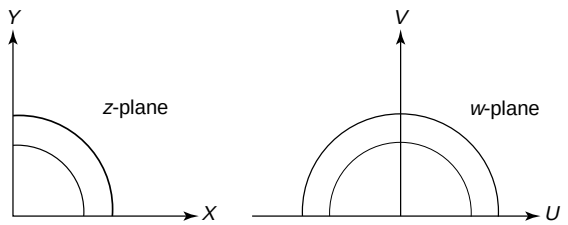

Fig. 1. Conformal representation.

Now suppose the two arcs in the z-plane coincide ($b = 0$) so that the figure becomes one quadrant and one semicircle, respectively. The mapping is no longer conformal at the origin, which is a singular point, for the magnification vanishes there and the angles become $\pi/2$ and π, respectively.

In a conformal representation, circles always transform into circles with straight lines as limiting cases. However, a hyperbola becomes a lemniscate, showing that the degree of the equation for the curve is not an invariant of the process.

See also **Mapping (Mathematics)**.

CONFORMITY. With reference to industrial and scientific instruments, the Instrument Society of America defines conformity (of a curve) as the closeness to which it approximates a specified curve (e.g., logarithmic, parabolic, cubic, and so on). Conformity is usually measured in terms of *nonconformity* and expressed as *conformity*; e.g., the maximum deviation between an average curve and a specified curve. The average curve is determined after making two or more full range traverses in each direction. The value of conformity is referred to the output unless otherwise stated. As a performance specification, conformity should be expressed as *independent conformity*, *terminal-based conformity*, or *zero-based conformity*. See Fig. 1. When expressed simply as conformity, it is assumed to be independent conformity. See also **Linearity**.

CONGENITAL ADRENAL HYPERPLASIA. See **Adrenal Disease**.

CONGER. See **Eels**.

CONGESTIVE HEART FAILURE (CHF). The general term heart failure is used to describe a limited ability of the heart to furnish a sufficient supply of oxygenated blood to meet the requirements of peripheral tissues, particularly when the heart is under heavy load as in exercise conditions. The word *failure* in this context does *not* connote *complete* failure, but rather a *partial* failure of varying degrees, depending upon patient, to function in a fully normal fashion under all reasonable demand situations. The term *cardiac insufficiency* is sometimes used to identify the same situation.

Congestive heart failure (a series of disorders) can arise from a variety of root causes and is one of the most common of heart ailments. A satisfactory explanation of all of the factors operative in congestive heart failure would require many pages of discussion pertaining to the physiology and mechanics of the heart. Generally, it can be observed that congestive heart

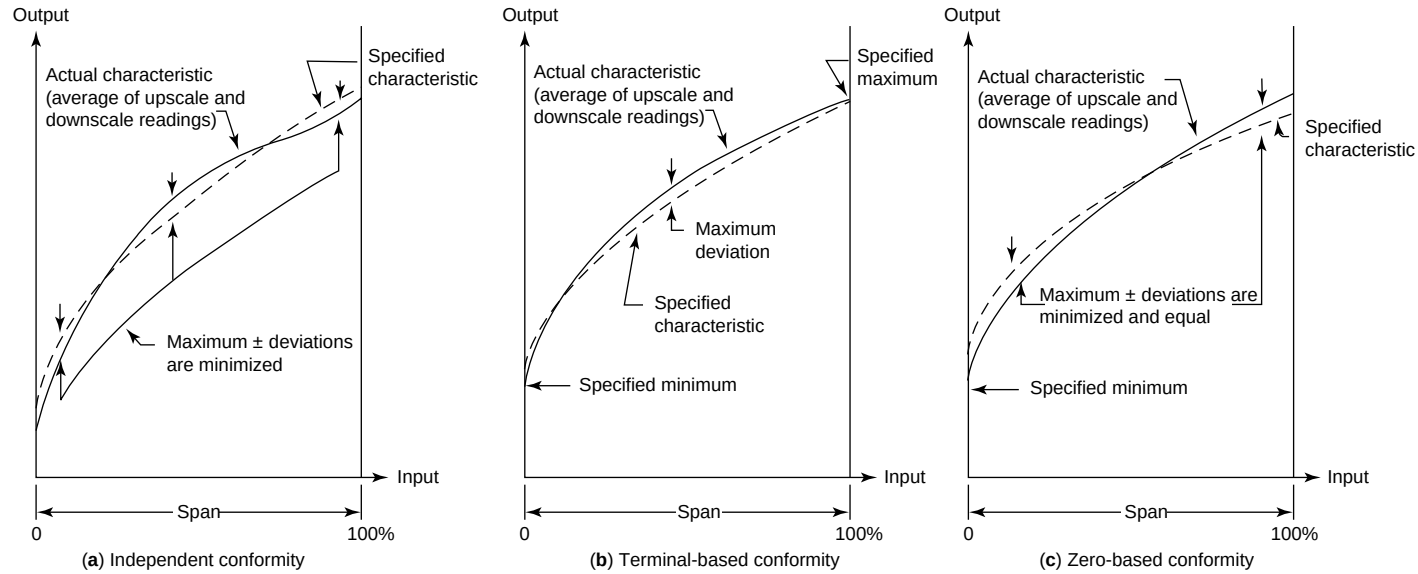

Fig. 1. Fundamental relationships pertaining to conformity.

failure results from factors that interfere with the heart muscle's adaptive (to load) mechanisms. There is essentially a loss of strength — a decreased ability to accomplish work — of the muscle. These adaptive mechanisms involve the contractility characteristics of the heart, for it is in contracting and expanding that the heart can function as a pump. See **Heart and Circulatory System (Physiology)**. One of the principal drugs used in the treatment of congestive heart failure is digitalis, an agent that increases the contractility of heart muscle. In a failing heart, when contractility is reduced, a lower stroke output is achieved relative to any given left ventricular filling pressure. The heart does not have full ability to match output with input. A normal heart will do more work, that is, it will increase cardiac output with an increase in left ventricular filling pressure. Further, a normal heart will change stroke volume to compensate for alterations in heart rate, that is, changes in heart rate will not significantly alter cardiac output. But, in the failing heart, in which there is a low basal cardiac output, the stroke volume will remain relatively constant and thus changes in heart rate are markedly affected by changes in cardiac output. In the total heart-circulatory system, these abnormalities cause profound problems.

Physiologists for many years have used the terms "left heart failure" and "right heart failure" to reflect two specifically different consequences. In left-side congestive heart failure, where the left ventricle is primarily involved, the left atrial pressure is elevated, leading to symptoms of pulmonary congestion and, in more advanced cases, acute pulmonary edema. In right-side congestive heart failure, the right atrial pressure is elevated, leading to symptoms of systemic venous hypertension and congestion. As congestive heart failure progresses, both sides ultimately are involved. The most common cause of right heart failure is left heart failure.

A person with congestive heart failure may have few symptoms if a normal life style is followed. But, unless diagnosed and treated, the condition tends to worsen. The condition also may be suddenly revealed as the result of some insult to the heart, such as acute myocardial infarction and, when present, congestive heart failure can seriously add to the complexities of recovery and survival.

In *left-sided congestive heart failure*, an early symptom is dyspnea, a feeling of breathlessness and increased effort required for breathing. While the mechanism is poorly understood, it is known that this dyspnea is related to increased interstitial pulmonary edema, which causes a stiffness of the lungs and hence a greater breathing effort. Exercise accentuates this condition. The physician will carefully differentiate this complaint from the condition of angina pectoris where a patient fears the pain of taking deep breaths and pants for air. Accurate diagnosis is of the utmost importance because the treatment of congestive heart failure differs markedly from that of angina pectoris. See also **Ischemic Heart Disease**. There are also numerous other factors unrelated to congestive heart failure that can contribute to dyspnea, such as lack of physical fitness, obesity, and chronic lung disease. Electrocardiography is frequently indicated.

A somewhat more definitive clinical feature of left-sided congestive heart failure is *orthopnea* (dyspnea that appears when the patient lies down). In congestive heart failure, orthopnea results from increased venous return to the heart, a condition that places extra commands on a failing left ventricle. However, persons with chronic obstructive pulmonary disease and obese people also frequently find that they can breathe easier when head and shoulders are elevated rather than in a prone position. A dry, nonproductive, hacking cough (*orthopneic cough*) that is relieved by sitting up is indicative of increased pulmonary congestion and is easily differentiated from the morning cough of bronchitis. For further confirmation, radiological studies may be indicated. There also may be paroxysmal nocturnal dyspnea. In this instance, the patient is sharply awakened after a few hours of sleep in an episode of gasping for air.

Acute pulmonary edema is the hallmark of more mature left-sided congestion. In this state, there is movement of fluid into the interstitial and alveolar spaces. See also **Respiratory System**. This condition can occur suddenly in persons with borderline pulmonary congestion with very frightening consequences — coughing, wheezing, breathlessness, intense anxiety, occasional slightly bloody sputum, and sometimes a feeling of impending death.

In *right-sided congestive heart failure*, an elevated right atrial pressure will lead to signs of systemic venous hypertension and congestion. The physician will carefully examine the neck veins. Distension of the neck veins (*hepatojugular reflux*), caused by increased venous return to the chest, is an indication of right ventricular dysfunction. In right-sided congestive heart failure, the liver usually enlarges. Edema is another common manifestation. This results from a passive venous congestion and retention of salt and water.

When congestive heart failure is first recognized, the physician will attempt to correct underlying causes. Drugs may be used to alleviate the problems of arrhythmias. See also **Arrhythmias (Cardiac)**. A pacemaker may be implanted in some patients; in others, consideration may be given to the surgical correction of certain congenital lesions that contribute to a failing heart. Attempts will be made to alleviate kidney problems. But if a patient still has problems after all conditions that may be reversible are treated, the long-term therapy will involve three basic approaches — salt restriction, digitalis, and diuretics. Because a failing circulation tends to retain salt, dietary input of salt will be controlled. This is a very difficult accomplishment with some patients. With the availability of stronger diuretics, there has been a trend toward relaxing the rules over minimizing salt intake daily. When a patient is in the hospital, an effort will be made to find a tolerable salt level with relation to the diuretics used. Of course, very tight control over salt intake is still required in the most severe cases of congestive heart failure. The role of diuretics is discussed in entry See also **Diuretics**.

The effects of *digitalis* for increasing contractility and cardiac output in congestive heart failure have been known since the late 1700s when Withering first described the qualities of foxglove. The exact manner in

which digitalis functions is not fully understood. However, it is suggested that the drug inhibits sodium-potassium activated ATPase (adenosine triphosphatase), thus reducing sodium and potassium transport across the plasma membrane and leading to an increase in intracellular sodium and an efflux of potassium from the cell (Smith and Haber, 1973). Accompanying the influx of sodium, there is an influx of calcium which is made available to the contractile element of the myofibril. It should be noted that, in the normal heart, digitalis not only increases contractility of the cardiac muscle, but also causes peripheral vasoconstriction, with no resulting marked change in cardiac output. On the other hand, in the failing heart of congestive heart failure, the heart is enlarged, with accompanying elevated peripheral vascular resistance. Digitalis in this instance reduces heart size, increasing cardiac output. This improves the heart's pumping efficiency, lowering oxygen consumption for a given amount of work done.

In recent years, digitalis prepared by leaf (foxglove) extraction has been largely replaced by the pure glycosides, *digitoxin* and *digoxin*. In North America, digoxin is probably the most commonly used. Since nearly 40% of the drug is excreted by the kidney each day, maintenance therapy requires replacement of that amount daily. When first administering digoxin, blood levels of the drug will be checked frequently and in about one week, an effective regimen for achieving and maintaining the proper level will be achieved. There are several side effects of the drug, known as digitalis toxicity. Symptoms include gastrointestinal disturbances, fatigue, headache, and dizziness. There may be disturbances in color vision. Sometimes the first sign of digitalis toxicity are cardiac arrhythmias, which require immediate attention and adjustment of drug blood levels, usually commencing with complete withdrawal of the drug until arrhythmias have been successfully resolved.

In addition to the foregoing drug therapies, in some patients the use of vasodilators may be indicated.

CONGLOMERATE. Conglomerate, called in older writings "pudding-stone," consists of aggregates of gravel or pebbles with a matrix of sand and cement. The proportion of pebbles and matrix may vary considerably both as to amount and actual or relative size of the component material. The common cementing materials are silica, calcite, and iron oxide.

Consolidated glacial debris called tillite, may consist of boulders of considerable size in a heterogeneous mixture of pebbles, clay and sand.

CONGRUENT. 1. Two geometric figures are congruent if they differ only in their position in space; that is, they are congruent with respect to a given geometry if they can be transformed into each other by transformations belonging to the group of the geometry; e.g., in Euclidean geometry by translations, rotations and reflections. 2. Two elements a, b of a ring are congruent *modulo m*, written $a \equiv b \pmod{m}$, if there exist elements p, q, r in the ring such that $a = mp + r$, $b = mq + r$; roughly speaking, if they leave the same remainder when divided by m. 3. Two square matrices A, B are congruent if A can be transformed into B by a congruent transformation; that is, if there exists a nonsingular matrix C such that $B = \hat{C}AC$, where $\hat{C}$ is the transpose of C.

See also **Matrix (Mathematics)**.

CONICAL COORDINATE. A degenerate curvilinear coordinate system obtained from an ellipsoidal coordinate system. The surfaces are: spheres with center at the origin of a rectangular system and radii u ($u = \text{const.}$); two sets of conical surfaces with apexes at the origin, one along the Z-axis and the other along the X-axis ($v, w = \text{const.}$). Conical coordinates are related to rectangular coordinates by the equations

$$x^2 = \frac{u^2 v^2 w^2}{b^2 c^2};$$

$$y^2 = \frac{u^2 (v^2 - b^2)(w^2 - b^2)}{b^2 (b^2 - c^2)}$$

$$z^2 = \frac{u^2 (v^2 - c^2)(w^2 - c^2)}{c^2 (c^2 - b^2)}$$

where $c^2 > v^2 > b^2 > w^2$.

CONICAL PROJECTIONS. The term applied to any one of that class of map projections in which the surface of the earth is projected from a point within the earth to the surface of one or more cones, and then developed on a plane. In the simple conical projection, a cone is placed tangent to the surface of the earth along the central parallel of latitude for the region to be mapped. The surface features are then projected onto the cone, the cone is cut along with an element that represents the meridian of longitude 180° from the central longitude of the mapped region, and the cone is rolled out on a plane. The resulting graticule will show parallels of latitude as circles concentric at the pole of rotation (usually outside the limits of the map), and meridians of longitude as straight lines converging on the pole.

Along parallels of latitude and along the central meridian, the scale of distance is uniform. The map is not conformal except close to the central parallel, and the distortion of shape increases rapidly with distance from that parallel. The simple conical projection is sometimes used for maps of small countries. For relatively large areas, the polyconic and Lambert projections are preferable conical projections.

CONICAL SURFACE. A surface generated by a moving line intersecting a fixed curve and passing through a fixed point. The line is the generatrix; the curve is the directrix; the point is the vertex; the generatrix in any position is an element of the surface. Its general equation, if the vertex is taken at the origin of a Cartesian coordinate system, is $Ax^2 + By^2 + Cz^2 + 2Fyz + 2Gxz + 2Hxy = 0$.

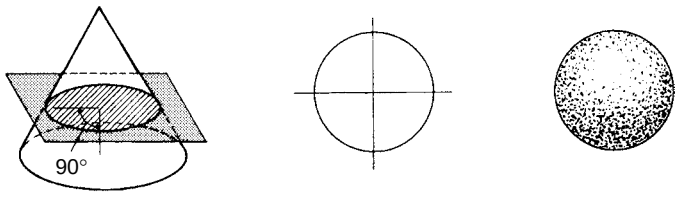
Depending on the curve chosen as the directrix, the surface is square, rectangular, elliptical, etc. If the directrix is an ellipse with semi-axes a and b and the generatrix is taken as the line $z = c$, the resulting equation is $x^2/a^2 + y^2/b^2 - z^2/c^2 = 0$. The axis of the conical surface is then the Z-axis and the coordinate origin is a center of symmetry. Two surfaces are thus produced, one for positive values of z and its mirror image for negative z. These are the two nappes of the conical surface.

If the directrix is a circle, $a = b$ and the surface is called right circular.

A cone is not identical with a conical surface for the former is a solid bounded by a closed conical surface and a plane cutting all of its elements.

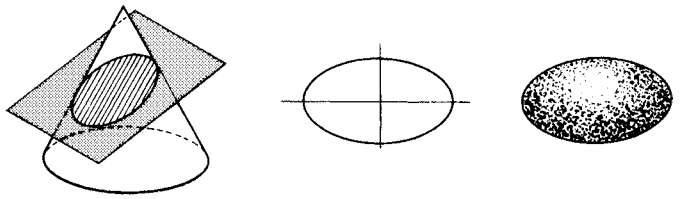
See also **Cone**; and **Conic Section**.

CONIC SECTION. The curve produced by a plane cutting a right circular conical surface, provided the plane does not pass through the vertex of the cone. The possible results are: an ellipse (or a circle as a special case) if the plane cuts all elements of one nappe of the cone; a



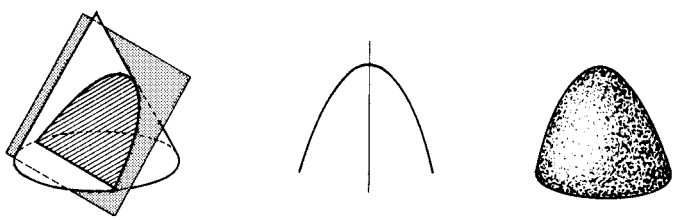
(**a**) (**b**) (**c**)

Fig. 1. (**a**) Plane cuts a right circular conical surface to form circle; special case of the ellipse where plane is 90 degrees to axis of cone: (**b**) circle; (**c**) sphere.



(**a**) (**b**) (**c**)

Fig. 2. (**a**) Plane cuts a right circular conical surface to form an ellipse. The plane cuts all elements of one nappe of the cone; (**b**) ellipse; (**c**) ellipsoid.



(**a**) (**b**) (**c**)

Fig. 3. (**a**) Plane cuts a right circular conical surface to form a parabola. Only one element of the cone is cut; (**b**) parabola; (**c**) paraboloid.

parabola if the plane cuts only one element of the cone; a hyperbola if the plane cuts both nappes of the cone. See Figures 1 through 4.

A conic section may also be defined as the locus of a point that moves so that its distance from a fixed point, the focus, is in a constant ratio, the eccentricity, to its distance from a fixed straight line, the directrix. A chord passing through a focus and perpendicular to an axis of the curve is the latus rectum.

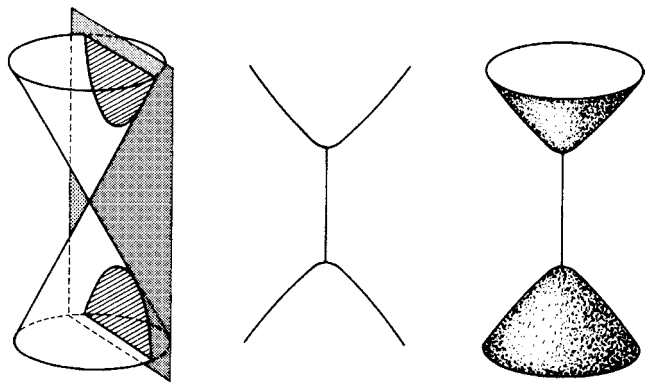
In Cartesian coordinates, a conic section is an algebraic equation of the second degree in two variables $Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$. The shape of the curve is determined by the parameters $A, B, \ldots, F$ and certain limiting forms, called degenerate conics, may occur. These are a point, one or two straight lines, a circle, or an imaginary locus. The quantities which determine the possible cases are the invariant of the equation, I and the discriminant, Δ. These are given by the equations $I = (B^2 - 4AC)$:

$$\Delta = \tfrac{1}{2}\begin{vmatrix} 2A & B & D \\ B & 2C & E \\ D & E & 2F \end{vmatrix}$$

The results are given in accompanying table.

1	Δ	Nature of Curve
0	$A\Delta < 0$	Ellipse; circle if $B = 0$, $A = C$
	$A\Delta > 0$	Imaginary locus
	0	A point
<0	$\neq 0$	Hyperbola
	0	Two intersecting straight lines
>0	$\neq 0$	Parabola
	0	$A \neq 0$; $H = D^2 - 4AF = 0$, one line; $H > 0$, two parallel lines; $H < 0$, imaginary locus; $A = 0$; $J = E^2 - 4CF = 0$, one line; $J > 0$, two parallel lines; $J < 0$, imaginary locus.

The equation of a conic section in polar coordinates is $r = ep/(1 - e\cos\theta)$, where e is the eccentricity, p is the distance from the focus to the directrix, the pole is at the focus, the polar axis is perpendicular to the directrix, and (r, θ) is any point on the curve.



(**a**) (**b**) (**c**)

Fig. 4. (**a**) Plane cuts a right circular conical surface to form a hyperbola. Both nappes of the cone are cut; (**b**) hyperbola; (**c**) hyperboloid.

If the conic section is symmetric about a finite point on the plane of the curve it is a central conic. Moreover, this point called the center can be chosen at the origin of a Cartesian coordinate system and, in that case, the equation contains no terms of the first degree in x and y. The central conics are the hyperbola and the ellipse, but a parabola is a noncentral conic since its center is at infinity.

A system of two conics having the same foci is a system of confocal conics. Its equation in standard form is $x^2/(A - q) + y^2/(B - q) = 1$, where $A > B$ and q is a variable parameter. If q is less than B or negative, both terms on the left are positive and the resulting curves are ellipses; if $A > q > B$, the curves are hyperbolas; if $q < A$, the curves are imaginary.

It is easy to see that the two families of conics have the same foci, for the distance from the center to the focus is $\sqrt{(A - q) - (B - q)} = \sqrt{(A - B)}$., in both cases. Through every point in the plane two curves intersect and the curves are mutually perpendicular at that point. Thus, if the point of intersection is described by the two real roots of the quadratic equation in q, these numbers locate the point in a two-dimensional curvilinear coordinate system (see also **Ellipsoidal Coordinate**).

A degenerate case of these conic families is a system of two sets of parabolas, opening in opposite directions. Since the curves are mutually perpendicular, they also may be used as a curvilinear coordinate system in two dimensions. The name parabolic coordinates is used for this system as well as for the three-dimensional case obtained by revolving the parabolas about their common axis.

See also **Cone**; and **Conical Surface**.

CONIDIA. A conidium is an asexual spore, characteristic of many fungi. Commonly it is formed at the tip of a hyphal branch, which is called a conidiophore. Conidia may be one- to many-celled.

CONIFERS. One of the two basic groups of trees; the other is the Broadleaves. There are about 650 species of conifers, contained within about 50 genera, and 8 families. The conifers include the dominant evergreen trees of the Northern Hemisphere, as well as some tropical species. Generally, conifers are trees, often of great size. Many attain a great age, as for example the Giant Sequoias and coast redwoods of California and Oregon, and the Douglas firs of the Pacific Northwest.

While they are dominant plants in the northern forests of today, in Mesozoic times they were much more numerous and often of much greater size. The Petrified Forest of Arizona contains a fossil Gymnosperm, *Araucarioxylon arizonicum*, from the Triassic period. As recently as the Miocene age, coniferales were much more widely scattered than at present, species of Redwood and Cypress growing in regions as far north as Greenland; today they are found only in warmer climates and often in a very restricted range there. Though naturally restricted in habitat, many of them are easily introduced into new, often distant regions, where they thrive.

The plant body of the conifers varies from low straggling shrubs to large trees. The several parts of the plant also show great diversity. Nearly all of them have tall straight stems extending to the very top of the tree, and numerous lateral branches that are progressively shorter from bottom to top of the trees, which therefore give an attractive conical shape. In many species there is a central taproot extending deep into the ground, from which smaller lateral roots arise. In other species extensive lateral roots spread out near the surface of the ground. The leaves of conifers of the Northern Hemisphere are either slender and needle-shaped or short and scale-like. See Fig. 1. Those of the pines are formed in fascicles or bunches of 2–5 which grow from a very short lateral branch. In spruces and firs the leaves are borne singly around the stem. In white cedar and certain other conifers the leaves are reduced to short pointed scales, which are formed in pairs on opposite sides of the stem, and are pressed tightly to it. In the Southern Hemisphere there are several conifers with broad leaves very similar in outward appearance to those of many angiosperms. The leaves of conifers have an epidermis of thick-walled cells that give stiffness to the leaves. The stomata are sunk deep in grooves. The chlorenchyma of the leaves, the cells containing the chloroplasts, is formed of cells the walls of which are curiously infolded. These cells surround the central vein, in which are found the vascular bundles. Some species have one, others two bundles in a leaf. In the chlorenchyma, numerous resin canals are found. These are also present in the bark and in the wood of many gymnosperms. The leaves of most gymnosperms remain on the tree from 2 to 5 or more years, and even, in some species, persist for as long as 20 years. Those of the larches are deciduous, falling in the autumn, and leaving the branches bare through the winter.

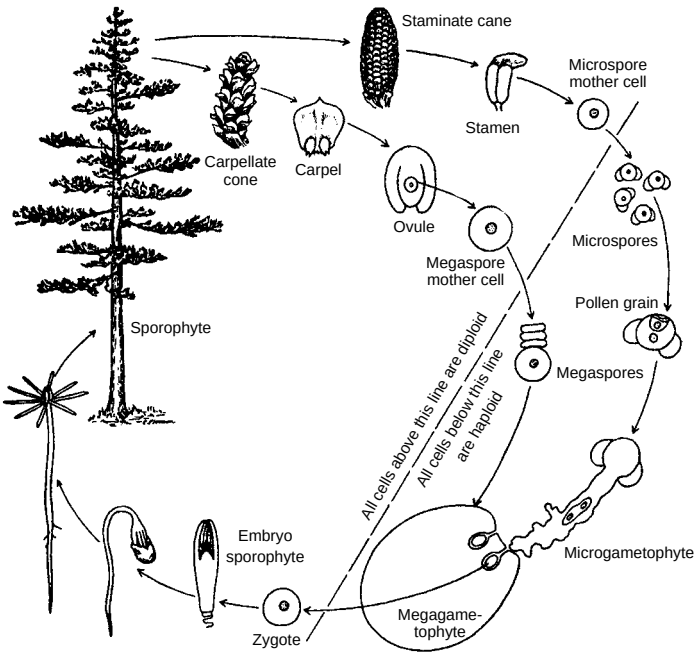


Fig. 2. Life cycle of a pine tree. (*A.M. Winchester*.)

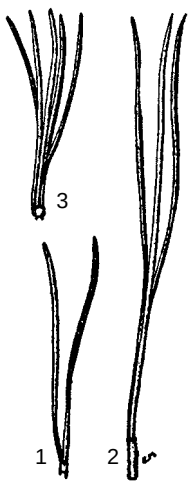

Fig. 1. Leaf clusters from different species of pine: (1) *Pinus murrayana*; (2) *Pinus ponderosa*; (3) *Pinus flexilis*.

The reproductive structures of the conifers are the cones or strobili, which are of two kinds, staminate and ovulate cones. See Fig. 2. Usually these are found on the same tree, which is therefore monoecious. The staminate cones, often called the male cones, are small and short-lived. They are generally found in clusters near the tips of the branches. A staminate cone consists of a central axis and a series of spirally arranged microsporophylls. Each microsporophyll bears two pollen-sacs or microsporangia on its lower surface. Each microsporangium contains numerous cells called microspore mother cells, which divide by meiosis to form haploid microspores, or pollen grains, four from each microspore mother cell. The number of pollen grains produced is tremendous; often they are liberated from the sporangia in such quantities as to produce what are known as "sulfur showers," which cover the ground with a layer of yellow pollen, or cause the water of ponds to become turbid with the pollen grains. The pollen is carried about by the wind, often to distances of many miles. The wall of a pollen grain is composed of two layers, an inner, called intine, and an outer, exine layer. In some conifers the outer layer is separate from the inner in two places, forming conspicuous balloon-like structures which presumably are an aid in keeping the pollen grain floating in the air. Even before shedding, the nucleus of the pollen grain has divided, so that grain at the time of shedding contains three or more cells. All but one of these are very small and last but a short time before they disintegrate, leaving thin disk-like cells pressed against one side of the pollen grain. These small cells are usually called prothallial cells, and are thought to be vestiges of extensive vegetative tissue or earlier forms. The large cell of the pollen grain divides to form two, known as the generative and tube cells.

The ovulate cones require a much longer time than the staminate to reach maturity. See Fig. 3. Often they remain on the tree for many years. The structure of the ovulate cone varies in the different genera, and is the cause of much discussion in many cases. In the pines, the genus in which the development of the ovulate structure is best known, the cone is made up of numerous scales. On the upper surface of each scale there are two ovules. The greater part of each ovule is a mass of cells called the nucellus or megasporangium. This is surrounded by an integument, a tissue which does not completely enclose the nucellus, a small opening known as the micropyle being left. It is through this opening that the pollen grains reach the surface of the megasporangium. As the ovule develops, one or sometimes more of the cells in the nucellus becomes distinct from the other cells because of its larger size and denser protoplasm. This is the megaspore mother cell. It divides by meiosis to form a row of four cells, one of which becomes the megaspore, the others degenerating. The single megaspore divides into many cells, which form the female gametophyte or megagametophyte. At the end of the megagametophyte nearest the micropyle several archegonia develop. Each archegonium contains a single very large egg cell.

The pollen grain, carried by the wind, comes in contact with a small drop of fluid, which has been secreted by cells in the region of the micropyle. As this evaporates the pollen grain is drawn down into the micropyle to the surface of the nucellus. There the pollen grain puts out a pollen tube, which grows through the nucellus tissue until it reaches the tip of the megagametophyte. During this development a final division of the generative nucleus has occurred, and two male gametes or sperm nuclei are formed. When the tip of the tube reaches an archegonium these nuclei are discharged into the egg. One of the nuclei passes to the egg nucleus and fuses with it; the other disintegrates. The time required for the pollen tube to reach the egg varies greatly in different genera; in some, like the spruce and the hemlock, it is a matter of a few weeks; in others, like the pine, it is nearly a year.

The nucleus of the fertilized egg passes to the basal end, dividing twice, and forms a rosette of four nuclei. Each of these divides again, forming two tiers of four nuclei. Walls then begin to form, separating the apical tier from the other. Subsequent nuclear divisions increase the number of tiers to four, each composed of four cells. The apical tier presently divides and forms the embryo; the second tier, called the suspensor, elongates greatly,

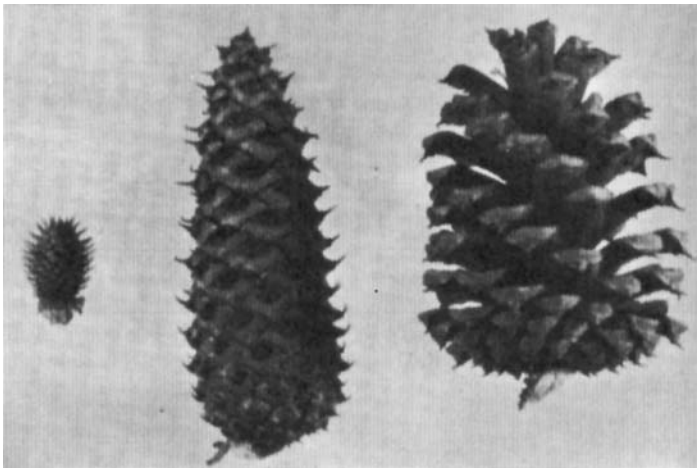

Fig. 3. The female (carpellate) cone of the loblolly pine, *Pinus taeda*. (Left) the small spring cone; (Center) the one-year-old cone containing the developing seed; (Right) the two-year-old cone, which has opened and allowed the winged seeds to escape. (*A.M. Winchester.*)

shoving the embryo down into the gametophyte tissue. There the embryo absorbs food substances from the tissues around it and matures.

The mature seed of a gymnosperm consists of a hard seed coat, developed from the integument, the nucellar tissue, and the embryo. See Fig. 4. The latter consists of a straight slender hypocotyl and two or more cotyledons, and a very small epicotyl or plumule. During its development this embryo has been surrounded by a mass of tissue called the endosperm, which is megagametophyte tissue.

Fig. 4. Pine seeds. The flattened wing attached to the main portion of the seed is a great aid to seed dispersion. (*A.M. Winchester.*)

The seeds of different conifers vary greatly in size. In some species of pine, they are large enough to be used as food for human beings. In the southwestern United States there are several species of pine which bear edible seeds. These are called piñon nuts, and are used in the same way as peanuts are. In southern Europe other species of pine yield edible seeds. One of these, called pignolea nuts, is frequently used in confectionery.

The conifers yield many other valuable products. The wood of many of them is extremely valuable, forming the principal timber used in construction work. Its use in this work is largely due to its composition. Each annual ring is composed of two distinct layers, an inner soft layer and an outer hard layer often much darker colored than the other; these give the wood great strength and also flexibility, and allow easy driving of nails into the wood without splitting it. The wood is also used for paper pulp. Turpentine and resin are obtained from many of the conifers. Amber is a fossil resin coming from an extinct conifer. Many conifers are grown as ornamental trees, often in regions far from their natural habitat.

Numerous conifers are described in specific entries in this volume. See the following:

Arborvitae	**Hemlock Trees**	**Podocarps**
Cedar Trees	**Juniper Trees**	**Redwood (Coast)**
Cypress Trees	**Maidenhair Tree**	**Spruce Trees**
Fir Trees	**Palm Trees**	**Yew Trees**
Giant Sequoia	**Pine Trees**

CONING. The nearly equal vertical and lateral dispersion of air pollutants from the centerline of a smoke plume, which occurs in statically neutral conditions. See also **Static Stability**.

As pollutants from a point source are blown downwind, the envelope of the smoke plume (as visible by eye or as measured by the percentage decrease of concentration from that at the centerline) takes the shape of a cone. Conversely, observation of a coning smoke plume can be used as an indicator that the ambient air there is statically neutral.

CONJUGATE. 1. A special kind of singular point of a plane curve. (See also **Conjugate Point (Mathematics)**.) 2. If $u + iv$ is a complex number or a function of a complex variable, its conjugate is $u - iv$. 3. For use of the word in group theory, see also **Transform**.

CONJUGATE DIRECTIONS (at a Point *P* on a Surface). The directions of the straight line joining P to a neighboring point Q on the surface, and the line of intersection of the tangent planes at P and Q, in the limiting case as Q tends to coincidence with P. If these two directions are the same, the direction is said to be a *self-conjugate direction*, or *asymptotic direction*. There are two real asymptotic directions at each point of a surface for which the two principal curvatures are of opposite signs. If the two principal curvatures have the same sign then the two asymptotic directions are imaginary. If one of the principal curvatures is zero, the two asymptotic directions at the point coincide.

See also **Surface**.

CONJUGATE ELEMENTS OF A GROUP. In a group G an element a is said to be conjugate to an element b if there exists an element p in G such that $b = pap^{-1}$. The relation of conjugacy is easily proved to be an equivalence, so that the whole group G is thereby divided into conjugate classes. A subgroup N is called a *self-conjugate*, or *normal*, subgroup if all the conjugates of every element of n (that is, all elements of the form pap^{-1} with a in N and p in G) are included in N.

See also **Permutation Group**.

CONJUGATE NUMBERS. Two algebraic numbers are conjugate over a given field if they are roots of the same irreducible equation with coefficients in the field. Thus the complex numbers $a + bi$, $a - bi$ *are conjugate over the real field, since they are roots of the equation* $x^2 - 2ax + (a^2 + b^2) = 0$.

CONJUGATE POINT (Mathematics). A singular point on a curve which is the real intersection of imaginary branches of the curve. The condition which must be met is

$$\left(\frac{\partial^2 f}{\partial \times \partial y}\right)^2 - \frac{\partial^2 f}{\partial x^2}\frac{\partial^2 f}{\partial y^2} < 0$$

CONJUGATE SOLUTIONS. A system in equilibrium consisting of two liquid phases and two components; if the components of such a two-component system are designated as A and B, then one phase is a solution

of component A in component B, and the other phase is a solution of component B in component A. Such liquids are spoken of as "partially miscible."

CONJUGATION. A form of sexual reproduction marked by the union of cells and the mingling of nuclear material. In the algae, *Spirogyra* (Fig. 1), one filament unites with another filament by means of conjugation tubes that connect the cells. The protoplasm of each cell becomes an isogamete. The isogametes from the cells of one filament migrate down the conjugation tube into the cells of the other filament. The union of gametes forms zygotes. Conjugation is also found in yeasts, bread mold, bacteria, and other simple plants. In animals, conjugation in *Paramecium* (Fig. 2) has been studied extensively. After a series of nuclear divisions and disintegrations, a half nucleus from one cell migrates into another cell and in turn receives a half nucleus from its partner. This achieves a variation in heredity, which would not be possible if reproduction was by asexual means only.

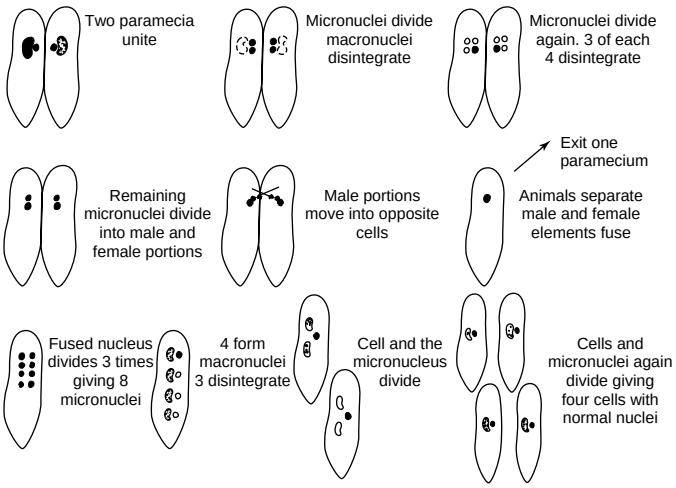

Fig. 2. Sexual reproduction by conjugation in *Paramecium caudatum*. (*A.M. Winchester*.)

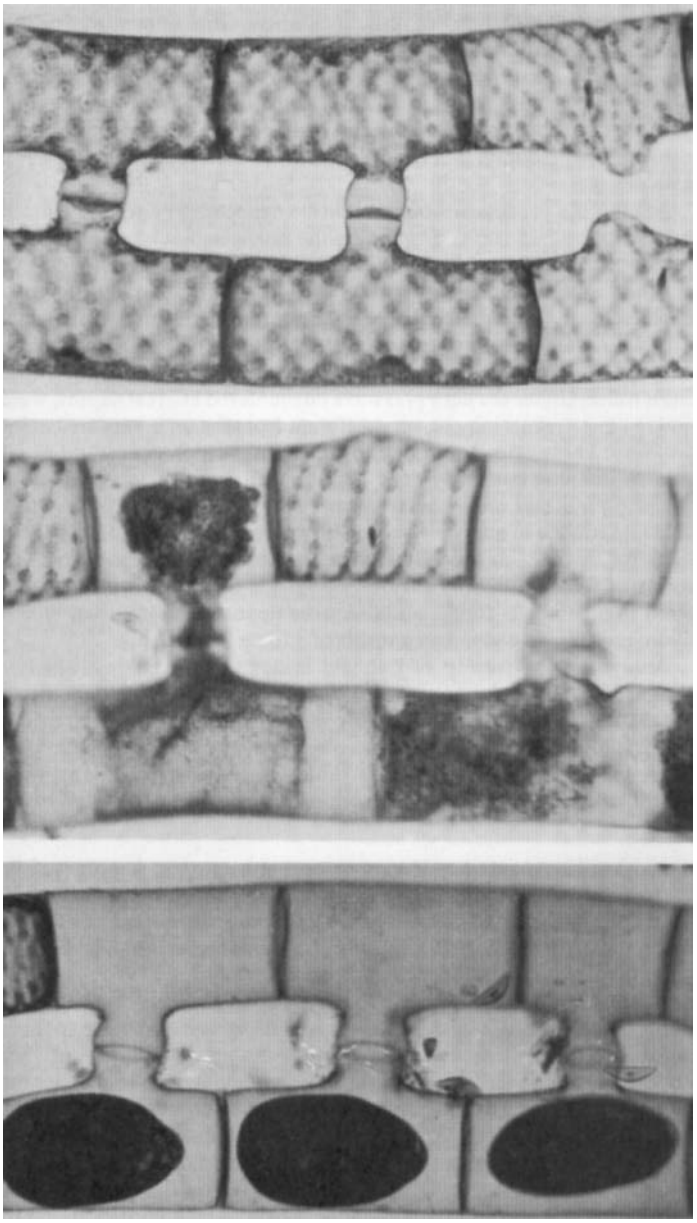

Fig. 1. Conjugation in *Spirogyra*: (Top) Gametes can be seen forming in the cells and the conjugation tubes are forming; (Middle) There is a union of gametes as those from one filament pass through the tube into the cells of the other filament; (Bottom) The zygotes have been formed. (*A.M. Winchester*.)

CONJUNCTION (Astronomy). When two heavenly bodies occupy the same longitude (same degree of the Zodiac), the bodies are said to be in *conjunction*. This is a condition when the same perpendicular to the ecliptic passes through both bodies. Should both bodies have, at the same time, an identical latitude (equally far north or south of the ecliptic), the one body will fully or partially block the view of the other body from the earth. If the observer were at some other location, that is, on the moon, on a planet, or in an orbiting astronomical observatory, as examples, the phenomenon of conjunction also would occur whenever the celestial geometry from that point was right. A conjunction as observed from the earth is termed *geocentric*; as it may be observed from the sun, *heliocentric*.

Conjunctions are most frequently mentioned in connection with the planets and asteroids. With reference to Fig. 1, note that the inner circle represents the orbit of an inner planet (Mercury or Venus). The middle circle is the earth's orbit. The outer circle represents the orbit of an outer planet (Mars, Jupiter, etc.). The angle at the earth between the lines drawn to a planet and the sun is known as the *elongation* of the planet. If the earth is at *E* when the inner planet is at *a*, the planet is said to be in *superior conjunction*. When the inner planet is at *b*, the planet is said to be in *inferior conjunction*. When the planet is at *g* or *h*, it is at its *greatest elongation*. The outer planet is in conjunction when at *c*; and in *opposition* when at *d*; and in *quadrature* when its elongation is 90 degrees, as noted at *e* and *f*. Elongations are termed *east* or *west*, depending upon the direction of the planet from the sun.

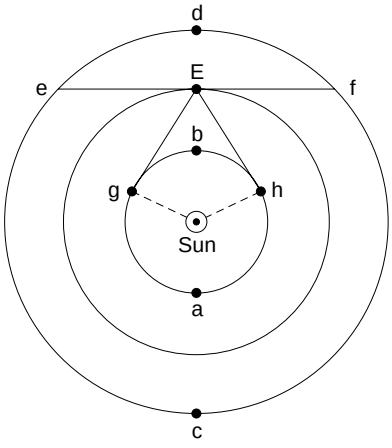

Fig. 1. Mechanics of conjunction.

A *grand conjunction* occurs when 3 or more planets or stars are observed together. In explaining the Star of Bethlehem, the conjunction theory is sometimes proposed and, provided some logical adjustments in the calendar then used are made, the proposition appears feasible. A grand conjunction is mentioned in Chinese historical records as having occurred about 2500 B.C. The term conjunction is sometimes used when two bodies,

such as Venus and the moon, appear in very close proximity as viewed from the earth. Astronomers normally forecast conjunctions as they will be viewed from the center of the earth.

CONJUNCTIVA. The conjunctiva is a transparent mucous membrane that covers the sclera, which is the white of the eye. The conjunctiva lines the inner surfaces of the eyelids. Comprised of many small blood vessels, the tiny secretory glands in the conjunctiva produce tear film that lubricates and protects the eye while it moves in its socket. When the eye is irritated, injured, or infected, these blood vessels dilate making the white part of the eye look red.

Bacteria and virus can inflame the conjunctiva, often leading to a condition called conjunctivitis. Although the conjunctiva is normally a tough, resilient tissue, in cases of ocular trauma, it may be lacerated with sharp or pointed objects such as fingernails, tree branches, or the edge of a piece of paper.

The conjunctiva is composed of three sections or regions: (1) The palpebral, which lines the under-surface of the eyelids; (2) The bulbar, which covers the front, external eyeball, and (3) The fornix which forms the junction between the eyelid and eyeball.

The palpebral is moderately thick, while the bulbar is very thin and movable, easily sliding back and forth over the front of the eyeball it covers. Because the bulbar is clear, it is easy to see underlying blood vessels. Within the bulbar, conjunctivae are "goblet cells" that secrete an important component of the precorneal tear layer, which protects and nourishes the cornea. The fornix is a loose pocket of conjunctiva between the upper eyelid and the eyeball that permits the eyeball to rotate freely.

The conjunctiva produces mucous, a clear viscous fluid that lubricates the eyeball, as well as produces some tears, which helps keep the eye clean. However, most tears are produced by the lacrimal glands, which are located at the upper outer corners of each orbit, and spread a smooth layer of mucous and tears over the eye every time you blink. After you blink, the fluid spreads evenly over the eye and then flows into tiny canals in the lids that lead to the lacrimal sac, a pouch at the lower inner corner of each orbit. The mucous and tears from the lacrimal glands and the conjunctiva eventually drain through a passage into the nose.

Vision Rx, Inc., Elmsford, NY

CONJUNCTIVAL TUMORS. Conjunctival tumors affect the clear, membrane-like tissue that covers the white of the eye: the conjunctiva. Although these tumors are usually benign, they can occasionally be malignant and require immediate medical evaluation by an ophthalmologist.

Conjunctival tumors usually first appear as a spot or slightly raised area against the white background of the eye and are diagnosed by an eye doctor using a slit lamp. The only way to determine whether such a tumor is benign or malignant is to examine a portion of the tissue under a microscope. Although malignant tumors are seldom seen, they must be treated with either radiation or surgical removal.

Tumors that are malignant may have spread from another place in the body (metastasized). It is important to differentiate tumors that originated in or around the eye from those that have metastasized, because treatment options differ.

Melanoma: The most common malignant tumor in the eye is a melanoma, which usually occurs in adults or mature patients. Conjunctival melanoma appears as a brown or pink nodule on the white surface of the eye and carries a 20% risk for metastasis. Early treatment, while the tumor is still small, is very important because, in about half of the cases, it can invade other parts of the eye requiring extensive surgery.

Nevus: A nevus is essentially a small, flat mole made up of specific cells called nevus cells that are found in the skin and in eye tissues. These types of tumors do not interfere with tissue function and seldom develop into a malignant melanoma.

Primary Acquired Melanosis: This is a flat, brown pigmentation on the surface of the eye that generally occurs in adults. It does carry some risk of developing into a malignant melanoma.

Squamous Cell Carcinoma: This is a type of cancer that can occur on any skin surface, including the eye, where it appears as a pink nodule on the eye surface. It is malignant and can invade around the eye into the orbit and sinuses.

Lymphoma: These tumors look like salmon-colored patches on the eye and can be a sign of systemic lymphoma. A biopsy is usually performed to determine if the tumor is benign or malignant. Patients with lymphoid conjunctival tumors should have a complete medical examination.

Cyst: A cyst is defined as any type of thin-walled sac, usually containing a liquid or semisolid. Such a tumor can be normal or abnormal depending on the cause.

Inflammatory tumor: A tumor that usually develops from the body's protective response to injury, infection, or irritation.

Conjunctival tumors are often diagnosed by examination with a slit-lamp biomicroscopy. If small, these tumors can be photographed and followed for evidence of growth prior to treatment. Most treatments focus on avoiding large surgeries which may be associated with vision loss or loss of the eye. If a tumor is diagnosed as nonmalignant, it may require only observation. If it is a vascular tumor, it may need laser treatment.

If the tumors are raised or extend onto the cornea, a biopsy may be required. Current treatments for conjunctival cancers include surgical removal, cryotherapy (freezing), radiation therapy, and more recently, chemotherapy eye-drops. These eye drops are in the investigational stage for patients with conjunctival tumors. The entire eye surface is treated, and this treatment may decrease the chance of future scarring. Standard chemotherapy is used to treat systemic lymphomas. If the eye is the only site of the lymphoma, external beam radiation therapy may be used.

Conjunctival tumors are serious and, if left untreated, can invade the tissues around the eye, the sinuses, and the brain. It is critical to obtain an early diagnosis and treatment for any eye cancer problem. See also **Conjunctiva**; and **Slit Lamp**.

Vision Rx, Inc., Elmsford, NY

CONJUNCTIVITIS. The general term given to any inflammation or infection of the conjunctiva. This condition has innumerable causes and constitutes the most common eye disease of the Western Hemisphere. Most cases are caused by bacterial or viral infection. However, allergy, chemical irritation, and infection by fungus or parasites are sometimes responsible. Conjunctivitis occurs in connection with a number of diseases, including ankylosing spondylitis, epidemic typhus, erythema multiforme, gonorrhea, leptospirosis, meningococcal disease, and Reiter's syndrome, among others. Pharyngoconjunctival fever (swimming-pool conjunctivitis) is usually associated with adenovirus type 3 or 7, but has been reported with other types as well. Incubation period of the disease is 2 to 8 days. The disease is quite contagious and spreads rapidly among family members. Epidemic keratoconjunctivitis and hemorrhagic cystitis are also caused by adenoviruses. Fever, photophobia and a tendency for the eyes to tear are present. Corneal erosions can occur within 2 days and may be sufficiently deep to interfere with vision. Outbreaks of this condition sometimes occur in professional ophthalmological and optometrist centers. This disease was first discovered on the West Coast of the United States, among shipyard workers, during World War II. It is believed that the epidemic resulted from improperly sanitized equipment used in a medical facility for treating eye injuries. Acute hemorrhagic cystitis was first observed in Japan.

Acute catarrhal conjunctivitis ("pink-eye") is a term rather loosely applied to inflammations of the conjunctiva in children, although adults are also susceptible. Pink-eye is sometimes associated with irritation from smoke, dust, wind, or intense light, as from electric arcs.

In the acute, highly contagious form of pink-eye, the eyes are red and watery at first. Then pus begins to accumulate. The eyelids may smart, burn, or itch, and become stuck together overnight by the discharge. General swelling and puffiness often surrounds the eyes.

Pink-eye usually represents an infection of the conjunctiva by pneumococci or staphylococci, but occasionally the Kochs-Weeks bacillus is responsible. Because the cornea can become involved in certain epidemic forms of the disease, medical attention should be sought whenever an eye is persistently or acutely inflamed. This condition also may mask a more serious eye disease. If pink-eye is diagnosed, scrupulous care must be taken to avoid transmitting the disease to others, or to the opposite eye if only one eye is involved. Promptly treated, conjunctivitis usually responds readily to therapy and causes no permanent eye damage.

Ophthalmia neonatorum is any inflammation of the conjunctiva in newborn infants. The condition is acquired by contact with an infected birth canal during delivery of the infant. Gonococcus is usually the infecting organism. Most areas now require the routine use of preventive measures in the delivery room. In most hospitals, two drops of a 1% silver nitrate solution are instilled into each of the infant's eyes at birth. Penicillin also can be substituted. The use of such preventive measures at birth has

enormously reduced the incidence of eye damage and blindness resulting from ophthalmia neonatorum.

Trachoma is an eye disease that approaches the incidence of the common cold in some areas of the world. The condition occurs mainly under conditions of overcrowding and poor hygiene. The condition is characterized by large, clear "granulations" underneath the eyelids. Without sulfonamide or antibiotic treatment, trachoma eventually produces corneal damage and moderate to complete visual loss.

Pinguecula is a yellowish nodule of tissue that appears gradually on the conjunctivas of both eyes in some persons. These nodules are usually located on the nasal side of the iris and are relatively common among persons over 35 years of age. The nodules consist of hyaline and elastic tissue and generally no treatment is required.

See also **Vision and the Eye**.

CONNATE WATER. Water that is trapped in marine sediments at the time they are laid down in the sea is commonly called *connate water*. As the term implies, connate water is produced at the same time as the rock and constitutes a sort of fossil seawater.

When marine sediments are raised above sea level and subjected to the action of circulating meteoric water, their connate water and solutes are removed by leaching and flushing and carried back to the ocean. The flushing process however is slow in fine-grained and deeply buried sediments, and water that almost certainly owes its high content of dissolved ions to remnants of marine solutions is common in such environments. The water associated with petroleum commonly is saline and occurs in formations whose porosity and structure are generally unfavorable for extensive water circulation and coincident removal of solutes. Usually the salt dissolved in brines that occur in deeply buried rocks is considered to be of connate origin. See also **Petroleum**.

Many geological processes may have modified the composition of connate brines to produce their wide range. Obviously these alterations have been extensive. Some connate waters are essentially saturated or nearly saturated solutions of sodium chloride. Others contain large proportions of calcium as well as sodium and chloride. Although the composition of connate water gives few useful clues as to the composition of the ocean in past geologic periods, the ocean has evidently been rich in chloride for a very long time, and brines in which anions other than chloride are predominant cannot logically be ascribed entirely to a connate origin.

Among the processes which might be expected to alter the concentrations of ions in connate water are: the precipitation of solids such as calcite on mineral surfaces, the solution of rock minerals and evaporites, sorption and desorption of ions on solids, and the differential movement of water molecules and ions through clay and shale strata. The latter effect is equivalent to the ultrafiltration effect of certain types of membranes used in the reverse osmosis method of removing solutes from water. Under the high pressures encountered at great depths, water and ion movements may be very different from the ones expected at low pressure. These effects may possibly explain the high concentrations of solutes in some connate brines and the difference in ion content between such brines and ordinary seawater. Another factor of considerable importance in many places appears to be the biochemical reduction of sulfur from S^{6+} as found in sulfate ions to sulfur in the more reduced forms of free sulfur, polysulfides, or sulfide ions. The brines encountered in oil and gas fields, and the gases themselves, are often high in hydrogen sulfide content as a result of sulfate reduction.

Analyses of a variety of connate brines have been published by White, Hem, and Waring (1963). White (1957) has suggested criteria for distinguishing connate water by means of ratios of concentrations of certain of the dissolved ions to one another. In most connate water the ratios of bromide and iodide to chlorine are relatively high and ratios of potassium and lithium to sodium are low.

CONNECTING ROD. The common connecting rod is one of the four elements of the mechanism known as the slider crank chain. This mechanism consists of a base that carries two members, one that rotates while the other reciprocates. The connecting rod connects the reciprocating and rotating elements by means of pinned or hinged joints at its ends, the same constituting the connecting rod bearings. The importance of this mechanism, and of its elements, including the connecting rod, is that it is the basis for a large number of machines of great importance to modern civilization. This is probably due to the fact that in so many cases a reciprocating motion is produced where rotary is desired, and vice versa. Among the more common illustrations of the machines of which the connecting rod is a vital and important part are engines, pumps, compressors, punches, etc. A familiar example is the connecting rod of the gasoline engine. This engine derives its power from the push of the exploding gas against the reciprocating piston. One end of the connecting rod is joined to the piston by the wrist pin on which it has bearing. The other end of the connecting rod has a bearing on the rotating crank pin. Thus, the connecting rod has a composite motion: one end of it reciprocates, while the other rotates. It is subject not only to tension and compressive stress, but also, by virtue of its inertia, to transverse bending. Due to this latter factor, high-speed connecting rods are carefully designed so that their mass will not only be as small as possible, but so placed as to cause the least shaking forces. Commonly used sections are the solid rectangular, the I-beam, and the tubular. Almost all materials, including cast iron, brass, wood, steel, aluminum alloy, have at one time or another been used for connecting rods.

CONNECTIVE TISSUE. The connective tissues, as the name suggests, are primarily those that bind together, connect and support other structures. They are derived from the loosely arranged mesenchyme of the embryo and are characterized in the adult by the presence of various kinds of cells and of much intercellular substance, also in various forms.

In addition to bone and cartilage the connective tissues of the adult vertebrate include the loose irregularly arranged tissue which underlies the skin and occupies spaces between other organs. In this tissue lie cells that produce its own structures, blood cells, fat cells, and cells that become active in the repair of wounds. Between the cells is a soft matrix containing two kinds of fibers: white and elastic. The white fibers give tensile strength to the tissue and the elastic fibers give elasticity.

The other connective tissues are made up of certain of these structures. Thus tendons and ligaments are composed principally of parallel white fibers. Fibrous membranes may be either elastic or tough according to the fibers composing them.

Some of these connective tissues have other functions, which are not associative. Adipose tissue, for example, is composed largely of cells in which fat is stored.

Some minute parts of many organs are held together by a network of reticular tissue whose fibers run in all directions among the cells of the organ.

The development of these tissues is so extensive that if all other components of the body could be removed, its gross form would still be evident.

See also **Bone**; and **Collagen**.

CONNECTIVITY. A domain bounded by a smooth curve is said to be simply connected. Any closed curve in the domain can be shrunk to a point by continuous deformation without crossing the boundary. When more than one continuous arc is required to form the boundary, the domain is multiply connected and the minimum number of arcs required to form the boundary is the connectivity.

CONSANGUINITY. The genetic relationship of igneous rocks. Related groups of rocks that have been derived from a common magma and thus form a distinct petrographic province.

CONSENSUS AVERAGING. A method used to estimate the true value of a quantity with measured or observed values that have statistical fluctuations and outliers that are presumed to be due to measurement error, extraneous signals, or noise. The consensus averaging technique examines the set of all measured values and finds the largest subset with values within a predetermined interval of each other. If that subset has fewer than a predetermined number of values, then the entire set of measurements is rejected; otherwise, the selected subset is averaged to obtain an estimate of the true value of the measured quantity. For this technique to be valid, the true value must not change greatly during the time period over which the measurements are taken. Consensus averaging has been used in wind profiling to determine an estimate of the wind velocity from

several measurements of the Doppler shift of the radar signal, which is often dominated by noise and contaminated by interfering radio signals, airplanes, birds, etc.

CONSEQUENT STREAMS. The type of drainage pattern that develops on the initial slopes of a land surface newly exposed to erosion by running water. Some surfaces, such as coastal plains, are underlaid by sedimentary strata gently tilted in the direction of surface slope. If one of the parallel series of tilted formations is more resistant to erosion than the others, a cliff or cuesta will be developed. Stream valleys, which develop parallel to the cuesta, are called subsequent, and their tributaries, which cut back into the cuesta are called obsequent. See Fig. 1.

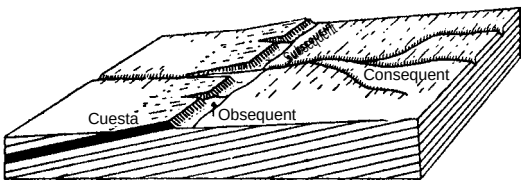

Fig. 1. Block diagram to illustrate the meaning and relations of consequent streams, in a youthful stage of the normal cycle of erosion in a region of tilted strata. The more resistant rock layer (in black) stands out in the form of a cuesta against the erosion.

CONSERVATION LAWS AND SYMMETRY. Basic among the natural laws are the so-called conservation laws which, in essence, state that in a given physical system under specified conditions there is a certain measurable quantity that remains changeless regardless of what actions may occur within the system. Three classical laws of this type are: (1) the law of the conservation of energy; (2) the law of the conservation of momentum; and (3) the law of the conservation of angular momentum. The concept of the conservation laws dates back to the early days of science and modifications have occurred and will continue to occur as new knowledge is gained. One of the tasks of physics is to explain the detailed rationale for laws that, on the surface, have a quality of being "self-evident."

An outstanding example of how these laws are subject to modification was Einstein's elucidation of the mass-energy equivalence ($E = mc^2$). Before that, the conservation of mass and the conservation of energy were considered to be independently valid.

General Functions of Laws of Conservation. An important function of the conservation laws is that they allow predictions about the behavior of a system without going into mechanical details of what happens during the course of a reaction. The laws provide a direct connection between the state of the system before the reaction and the state after the reaction. Also, one may conclude that any action that violates one of the conservation laws must be forbidden.

Laws of this nature are postulated as a result of many measurements of the energies and momenta involved in reactions of all kinds. It is always found that within the limit of accuracy of the experiment, for example, the amount of energy in the system after the reaction is the same as the amount of energy before the reaction. Prior to the development of elementary particle physics, there was much emphasis on transformation of energy between its various "forms," such as mechanical, electrical, and thermal energy. The present viewpoint is that the macroscopic behavior of matter is the result of interactions between elementary particles and that these elementary interactions individually obey the various conservation laws. In its elementary form, the law of conservation of energy states that when two or more particles interact, the total energy (kinetic plus potential) is always a constant. When it is said, for example, that the kinetic energy of a moving object has been transformed into the potential energy of a compressed spring, what is really meant is that, on a microscopic level, the atoms of the spring have been pressed closer together, so that there is a greater amount of potential energy in the electric fields between the atoms of the spring. This increase of potential energy is associated with an equal decrease in the kinetic energy of the object that caused the spring to compress.

Concept of Symmetry. With the development of the Lagrangian and Hamiltonian methods of solving physical problems, and particularly with the growth of importance of quantum mechanics, it became clear that the conservation laws are closely connected with the concept of symmetry in space and time. This is based upon the ability to describe the interaction between two or more objects in terms of a potential energy function. If the potential energy of the system is known for any position of these objects in space and time, then the future motions of the objects can be predicted. Certain predictions can be made without going through a complete solution of the equations of motion. For example, it is found that if the potential energy does not depend explicitly on one of the space coordinates, then the momentum associated with that coordinate does not change, but is a constant of the motion.

Some examples of "geometrical symmetries" encountered in classical physics might include:

1. An object moves in a 3-dimensional space where its potential energy is the same at every point. The expression describing the potential does not explicitly contain the coordinates x, y, or z. That is, the system is invariant with respect to translation of the origin of the coordinate system in any direction. This symmetry is associated with conservation of linear momentum; the momentum in all three dimensions is a constant.

2. An object moves in a world that is flat so that the force of gravity is in the vertical (z) direction. The potential depends only on the height of the object above the ground, but does not depend on its location in the horizontal plane; i.e., the potential is invariant to a translation of the coordinate system in the x-y plane. There is now symmetry in two dimensions, and momentum in the x-y plane is conserved.

3. In the interaction between two spherical bodies, if the potential depends only on the distance between the bodies, then there is spherical symmetry. The system is invariant to a rotation of the coordinate system about any axis. In this case, two components of angular momentum are conserved; as the two bodies orbit around their common center of mass, the magnitude of their angular momentum is constant, while the plane of the orbit in space does not change.

4. If the interaction between two objects does not depend explicitly on the time coordinate, then the actions that take place do not depend on when one starts to measure time; i.e., the properties of the system are invariant with respect to a translation of the origin of coordinates along the time axis. This symmetry is associated with conservation of energy. Use of a 4-dimensional coordinate system allows one to associate conservation of momentum and energy in a unified manner with the geometrical symmetry of space-time.

The conservation laws and the concept of symmetry acquired importance in the area of elementary particle physics. The conservation laws act as "selection rules" to determine which reactions may take place between the many existing particles out of the very large number of otherwise conceivable reactions.

An important property of elementary particles is *parity*. Each particle has a parity number associated with it; either $+1$ or -1, depending on the type of particle. In an assembly of particles, there is a total parity, which is the sum of the individual parities. If parity is conserved, then this total parity does not change during the course of the reaction. This property of matter is associated with the so-called mirror symmetry. All the laws of nature which possess this type of symmetry are such that if the words "right" and "left" are interchanged in the statement of the law, then the behavior of the system obeying these laws is unchanged. At one time, it was thought that every natural law was of this type. As a result of conservation of parity, it was believed that it would be impossible to describe the difference between "right" and "left" by the use of words alone. Yang and Lee (1956) pointed out that in a special class of reactions involving the "weak nuclear" interaction, parity need not be conserved. As a result of this finding, it was seen that the universe does possess an asymmetry between right and left and that it is possible to describe an experiment which will definitely distinguish between the directions "right" and "left" in the universe.

Another type of symmetry of importance in elementary particle physics is that entitled *charge conjugation*. This principle states that if each particle in a given isolated system is replaced by its corresponding antiparticle, then no difference can be observed. For example, if, in a hydrogen atom, the proton is replaced by an anti-proton and the electron is replaced by a positron, then this antimatter atom will behave exactly like an ordinary atom, so long as it does not come into contact with ordinary atoms.

However, it is found that there are certain types of reactions where this rule does not hold. These are the types of reactions where conservation

of parity breaks down. If one considers a piece of radioactive material emitting electrons by beta decay, the radioactive nuclei are lined up in a magnetic field which is produced by electrons traveling clockwise in a coil of wire (as seen by an observer looking down on the coil). Because of the asymmetry of the radioactive nuclei, most of the emitted electrons travel in the downward direction. If the same experiment were done with similar nuclei composed of antiparticles and the current in the magnet coil consisted of positrons instead of electrons, then the emitted positrons would be found to travel in the upward rather than in the downward direction. Thus, interchanging each particle with an antiparticle has produced a change in the experiment.

In the foregoing situation, however, the symmetry can be restored if the words "right" and "left" are interchanged in the description of the experiment at the same time each particle is exchanged with its antiparticle. In this example, this is equivalent to replacing the word "clockwise" by "counterclockwise." When this is done, the positrons are emitted in the downward direction, just like the electrons in the original experiment. The laws of nature thus have been found to be invariant to the simultaneous application of charge conjugation and mirror inversion.

Other more technical conservation laws play a role in elementary particle physics. Conservation of *baryon number* and *conservation of strangeness* are rules required to account for the fact that certain reactions involving heavy particles are forbidden. *Time reversal invariance* describes the situation that, in reactions between elementary particles, it does not make any difference if the direction of the time coordinate is reversed.

Although a symmetry idea may first suggest a conservation law, the conservation law must be tested by experiment to see if the symmetry is valid.

Conservation of Energy in Thermodynamics. The principle of conservation of energy plays a fundamental role in thermodynamics and is, therefore, also called the first law of thermodynamics. In its most general form it postulates the existence of a function of state, called the internal energy of the system U, such that its change per unit time is equal to some flow, called the energy flow from the surroundings.

This statement can be expressed symbolically by the formula

$$dU = d_e U \text{ or } d_i U = 0 \tag{1}$$

in which $d_e U$ is the energy received during the time dt from the outside, and $d_i U$ is the energy "creation" inside the system.

The explicit form of the energy flow depends on the nature of the system considered.

In closed systems and in the absence of an external field, the energy U supplied from the outside during the time interval dt is equal to the sum of the heat flow dQ expressed in units of energy and the mechanical work dW performed at the boundaries of the system. If the pressure is normal to the surface, the mechanical work is simply $-pdV$ and the expression of the energy conservation becomes

$$dU = dQ - p\,dV \tag{2}$$

From a purely phenomenological point of view, this expression of the conservation of energy may be considered the definition of the heat received by the system. The extension of the mechanical principle of conservation of energy to include the flow of heat is due mainly to Carnot, Joule, Helmholtz, and Clausius.

In order to express the energy conservation in continuous systems, it is useful to introduce the energy density per unit volume

$$u_v = \frac{\Delta U}{\Delta V} \tag{3}$$

In agreement with the general formulation of the principle of energy conservation

$$\frac{\partial u_c}{\partial t} = \text{div } \Phi[U] \tag{4}$$

where $\Phi[U]$ is the energy flow. This flow contains in general different contributions, among which are:

1. The convection flow corresponding to a center of mass motion ω, amounting to $u_v\omega$.
2. A heat flow Q.
3. A flow of energy corresponding to the pressure tensor p_{ij} in the fluid, its i component being
$$\sum_j p_{ij}\omega \tag{5}$$
4. A flow of potential energy (e.g., the outward flow of electromagnetic energy).
5. A flow of energy related to diffusion.

The total energy U may be split into an internal energy, a potential energy, and a macroscopic kinetic energy. Each contribution taken separately does not satisfy an equation of the simple form of Equation (4) because of possible transformation of one form of energy to another.

Conservation of Mass. This law has been put in the form that matter can be neither created nor destroyed. More accurately, the total mass of any system remains constant under all transformations. The statement, however, is subordinate to mass-energy equivalence.

Consider a homogeneous closed system containing c components ($\gamma = 1 \ldots c$) among which a single chemical reaction is possible. In such a system any variation in the masses will result only from the chemical reaction. Thus, the change of the masses m_γ of component γ during the time interval dt can be written as

$$dm\gamma = v_\gamma M_\gamma d\xi \tag{6}$$

where M_γ is the molar mass of component γ and v_γ its stoichiometric coefficient in the chemical reactions.

This coefficient is generally counted positive when v appears in the right-hand member of the reaction equation, negative when it appears in the left-hand member; ξ is the degree of advancement or extent of reaction.

The total mass of the system is given by $m = \sum_\gamma m_\gamma$. Summing over γ, the conservation of mass for a closed system is expressed by

$$dm = \left(\sum_\gamma v_\gamma M_\gamma\right) d\xi = 0 \tag{7}$$

The equation

$$\sum_\gamma v_\gamma M_\gamma = 0 \tag{8}$$

is called the equation of the chemical reaction or, more briefly, the stoichiometric equation.

Instead of the mass of the components it is often useful to consider the mole numbers $n_1 \ldots n_c$. Instead of Equation (6), this becomes

$$dn_\gamma = v_\gamma d\xi \tag{9}$$

Equations (6) and (9) are extended easily to r simultaneous reactions. The different reactions are designated by indices ($\rho = 1 \ldots 3r$). Instead of Equations (6) and (9), there are

$$dm_\gamma = M_\gamma \sum_{\rho=1}^{r} v_{\gamma\rho}\, d\xi_\rho \tag{10}$$

$$dn_\gamma = \sum_{\rho=1}^{r} v_{\gamma\rho}\, d\xi_\rho \tag{11}$$

where $v_{\gamma\rho}$ denotes the stoichiometric coefficient of γ in the reaction.

The conservation of mass in a continuous system is expressed by the equation of continuity for the density, ρ,

$$\frac{\partial \rho}{\partial t} = -\text{div } \rho\omega \tag{12}$$

where ω is the macroscopic velocity. This equation expresses the fact that the local change of the density is equal to the negative divergence of the flow of matter.

Equation (12) holds also for a mixture; ω is then related to the macroscopic velocities of the different components by

$$\omega = \left(\sum_\gamma \rho_\gamma \omega_\gamma\right) / \rho \tag{13}$$

Thus ω is simply the velocity of the center of gravity in an element of volume.

In general, the local change of a physical quantity is due not only to the divergence of the current which is associated with it, but a "source" term has also to be taken into account. For instance, the equation of continuity for the density ρ_γ of a component γ participating in a chemical reaction is

$$\frac{\partial \rho_\gamma}{\partial t} = -\text{div } \rho_\gamma \omega_\gamma + v_\gamma M_\gamma V_\gamma \tag{14}$$

where V_v is the rate of the chemical reaction per unit volume.

In an open system, it is possible to split the change of mass of component γ into an external part, $d_e m_\gamma$ supplied from the exterior, and an internal part, $d_i m_\gamma$ due to changes inside the system

$$dm_\gamma = d_e m_\gamma + d_i m_\gamma \tag{15}$$

Taking into account the equations on conservation of mass in closed systems, this becomes

$$dm_\gamma = d_e m_\gamma + M_\gamma \sum_{\rho=1}^{r} v_{\gamma\rho} d\xi_\rho \tag{16}$$

$$dn_\gamma = d_e n_\gamma + \sum_{\gamma=1}^{r} v_{\gamma\rho} d\xi_\rho \tag{17}$$

Summing Equation (16) over γ and taking into account the stoichiometric equations $\sum_\gamma v_{\gamma\rho} M_\gamma = 0$, the total change of mass is

$$dm = d_e m \tag{18}$$

This relation expresses the conservation of mass in open systems and indicates that the change of the total mass is equal to the mass exchanged with the outside world.

Conservation of Momentum. The principle of conservation of momentum states that for a dynamical system consisting of n material particles of masses $m_1, m_2, \ldots, m_n$, respectively, and position vectors $r_1, r_2, \ldots, r_n$, respectively, if the only forces acting are the mutual interaction forces of the particles the total momentum of the system remains constant; for example

$$\sum m_i \frac{d\mathbf{r}}{dt} = \text{constant} \tag{19}$$

The law of conservation of momentum is as fundamental to physics as the law of conservation of mass energy. Like that law, it holds in quantum mechanics and relativistic mechanics as well as in classical mechanics.

Conservation of Electric Charge. Since electric charge comes in discrete quantities (there is no known way of breaking an electric charge down into bundles smaller than that contained in an electron), this law deals with the counting of objects, rather than with the measurement of continuous variables, such as momentum or energy. Conservation of electric charge means that the total number of electric charges (taking positive and negative signs into account) in a closed system does not change. This, in earlier times, meant that electric charge could not be created or destroyed. The creation of charged particles is now spoken of, but the creation of a positive charge must always be accompanied by formation of an equal negative charge (e.g., an electron-positron pair is created by a photon). Conservation of electric charge is associated with a symmetry property of Maxwell's equations known as gage invariance which states that the absolute value of the electric potential (as opposed to the relative value) plays no part in physical processes. Further developments in quantum mechanics indicate that conservation of electric charge is connected with the observation that the properties of a system of particles do not depend on the phase of the wave function describing the system.

The following conservation principles apply particularly to interactions of elementary particles:

1. *The total baryon number remains constant*. A baryon is a nucleon (proton or neutron) or any particle heavier than those that can be considered to have an atomic mass number $A = 1$. Some mesons have a mass greater than the proton, but they have a mass number $A = 0$, so they are not baryons. In computing the number of baryons present in a system, each baryon counts 1; each antibaryon counts -1; and leptons and mesons count 0.

2. *The total lepton number remains constant*. Leptons consist of the neutrinos, electrons, muons, and their antiparticles. Here again, the basic principles applied are analogous to those for baryon number; particles count 1; antiparticles count -1; and baryons and mesons 0.

3. *Total strangeness quantum number*. This remains constant except as previously mentioned in connection with weak interactions.

CONSERVATIVE SYSTEM. 1. A closed system in which mechanical energy is constant is called a conservative system, as is an open system in which all external work is available as potential and kinetic energy of the system.

2. A system of particles in which the forces acting on any particle of the system are forces which can be derived from a potential energy function. There must exist a potential energy function $V(x, y, z)$ such that the components of the resultant of these forces are given by

$$F_x = -\frac{\partial V}{\partial x}, F_y = -\frac{\partial V}{\partial y}, F_z = -\frac{\partial V}{\partial z}$$

or the resultant force vector $\mathbf{F} = -\nabla V$. The forces that satisfy this condition are called conservative forces. In a conservative system, the work required to move a particle from one point to another depends only on the positions of the two points, not on the path followed between them.

CONSISTENCY. See **Rheology**.

CONSISTENT STATISTIC. A statistic is said to be consistent if when calculated from the whole population it gives the correct value of the population parameter. More precisely as the size of the sample n increases then

$$\lim_{n\to\infty} P\{|t - \theta| > \in\} \longrightarrow 0$$

that is, the probability that the statistic t differs from the population parameter θ by more than $\in$ in absolute value approaches zero. The least one should demand of a statistic is that it be consistent.

CONSOLUTE LIQUIDS. This term is applied to liquids when they are miscible in all proportions, i.e., mutually completely soluble, under some given conditions. It is not usually applied to gases because they are all miscible.

CONSOLUTE TEMPERATURE. The upper consolute temperature for two partially miscible liquids is the critical temperature above which the two liquids are miscible in all proportions. In some systems where the mutual solubility decreases with increasing temperature over a certain temperature range, the lower consolute temperature corresponds to the critical temperature below which the two liquids are miscible in all proportions. Some systems such as methylethyl ketone and water have both upper and lower consolute temperatures.

CONSONANCE. When two or more musical tones played simultaneously produce a pleasing effect on the listener, the tones are said to be in consonance. The general condition for consonance is that the frequencies of all the sounds have the ratios of small whole numbers.

CONSTANT. An absolute constant is a single number that always has the same value. An arbitrary constant or parameter is one that has only one particular value in a given case, but may have another value in another case. For example, the equation $x^2 + y^2 = r^2$ represents a circle. If r is an absolute constant, there will be one and only one circle described by this equation. However, if r is a parameter the equation represents the entire family of circles, infinite in number, which have their center at the origin of a Cartesian coordinate system. A given circle of

the family is found by the choice of r, which fixes the radius of the circle.

Arbitrary constants are frequently designated by letters from the first part of the alphabet, such as a, b, c, etc.

CONSTANT-CURRENT TRANSFORMER. This is a specially constructed transformer, sometimes called a tub transformer, built so the primary and secondary can move relative to one another under the influence of the forces set up by the load current. The currents in the primary and secondary react on one another to produce a repelling force between the two windings, the greater the current, the greater the force. The secondary is movable along the core and is partially balanced by a counterweight that is adjusted so the current forces will produce just the right reaction to hold the current essentially constant. An increase of current increases the force and hence the separation, which in turn increases the leakage flux between the windings and lowers secondary voltage. The lowered voltage causes a reduction of the current to a value which, when equilibrium is reached, is practically constant. Reduction of the load current causes an opposite sequence of reactions.

CONSTANT-LEVEL BALLOON. A balloon designed to float at a constant-pressure level. Also called *constant-pressure balloon*.

In one design for such a system, a pressure switch actuates a valve that controls the release of ballast so as to maintain flight above a selected pressure level until the supply of ballast is exhausted. Another design is a simple nonextensible envelope capable of withstanding a differential of pressure, higher inside than out. It is inflated so that the smaller night-time pressure of the gas still fully extends the envelope. Such a superpressure balloon will keep essentially constant level until enough gas diffuses out of it to allow diurnal changes in volumes. See also **Balloon**.

CONSTANT-PRESSURE CHART. See **Meteorology**.

CONSTELLATION PROGRAM. NASA's Constellation Program is getting to work on the new spacecraft and launch vehicles that will return humans to the moon and blaze a trail to Mars and beyond. See Fig. 1. Thousands of people across the agency are pulling together to meet this challenge, with work assignments that will sustain ten healthy and productive centers.

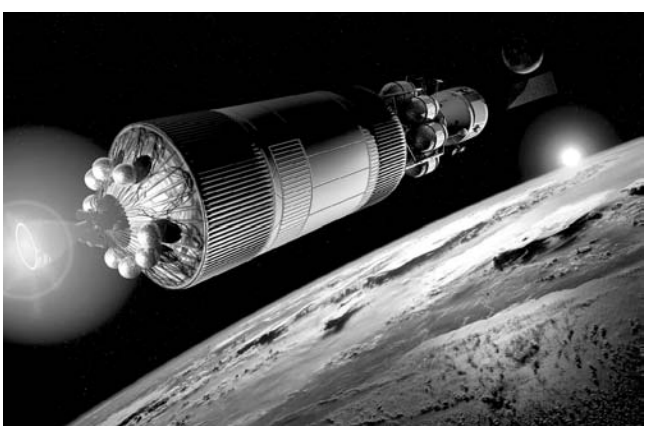

Fig. 1. An Earth Departure Stage, docked to the Crew Exploration Vehicle, fires its engine to leave Earth's orbit. **Click to enlarge**. (Image courtesy of NASA/John Frassanito and Associates).

Each NASA center is playing a vital role in making the Vision for Space Exploration a reality.

Ames Research Center, Moffet Field, CA. NASA Ames will be the lead for development of thermal protection systems and information technology for NASA's exploration effort. This responsibility includes developing the heat shield and aeroshell for the new spaceship called the **Crew Exploration Vehicle (CEV)**. See also http://www.nasa.gov/centers/ames/research/2006/orionheatshield.html.

The CEV is America's new spacecraft for human space exploration. It will be able to ferry crews of three astronauts (plus additional cargo) to and from the International Space Station, but has the capability to carry as many as six crew members. It will take four crewmembers to lunar orbit, and even return up to six crewmembers to Earth on the final leg of a human Mars mission.

NASA's new spaceship of the future must endure searing temperatures capable of melting iron, steel or chromium as the spacecraft streaks into the Earth's atmosphere on the way back from the moon.

Faster than the fastest bullet, the spaceship–called the **Orion**–will enter Earth's atmosphere at 6.8 miles (11 kilometers) per second, generating surface temperatures equivalent to more than 4,800 degrees Fahrenheit (2,649 degrees Celsius.)

The shuttle enters the atmosphere at lesser speeds, 4.7 miles (7.5 kilometers) per second, generating a lower maximum temperature of 2,900 degrees Fahrenheit (1,593 degrees Celsius) —still hot enough to melt nickel and iron. The crew vehicle will see temperatures of as much as 3,400 degrees Fahrenheit (1,871 degrees Celsius) when re-entering from low-Earth orbit. The length of spacecraft re-entries is also a variable. Because re-entry times vary, the duration of these periods also affect how a heat shield reacts to high temperatures.

Scientists and engineers at NASA Ames Research Center, located in California's Silicon Valley, are leading NASA's Orion advanced heat shield development effort. It is officially called the **Thermal Protection System Advanced Development Project (TPS ADP)**.

They're also leading the development of the Lunar Crater Observation and Sensing Satellite.

NASA will send an impactor spacecraft to the moon with the launch of the Lunar Reconnaissance Orbiter, scheduled for October 2008. The Lunar Crater Observation and Sensing Satellite will travel independently of the orbiter and crash into the lunar surface to search for water ice.

First, the craft will direct the upper stage used to leave Earth orbit to crash into a permanently-shadowed crater at the lunar south pole, creating a plume visible to Earth-based observatories. Next, the satellite will observe the plume and fly through it using several instruments to look for water. At the end of its mission, the satellite will itself become an impactor, creating a second plume visible to lunar-orbiting spacecraft and Earth-based observatories.

The Lunar Reconnaissance Orbiter is the first of many robotic missions NASA will conduct between 2008 and 2016 to study, map, and learn about the lunar surface as we prepare to return astronauts to the moon. Early missions like this one will help determine potential lunar landing sites and explore whether resources, such as oxygen, hydrogen, and metals, are available.

Dryden Flight Research Center, Edwards, CA. Dryden will lead the abort flight test integration and operations for the CEV. The center will support abort systems tests, drop tests, landing and recovery tests, flight re-entry and landing profiles and range safety. See also http://www.nasa.gov/centers/dryden/home/index.html.

Glenn Research Center, Cleveland, OH. Glenn will manage the work on the CEV's service module, which will provide maneuvering with its propulsion system, generate power using solar arrays, and keep the vehicle cool with heat rejection radiators. See Fig. 2. Glenn is also the lead for the upper stage of the Crew Launch Vehicle. See also http://www.nasa.gov/centers/glenn/home/index.html.

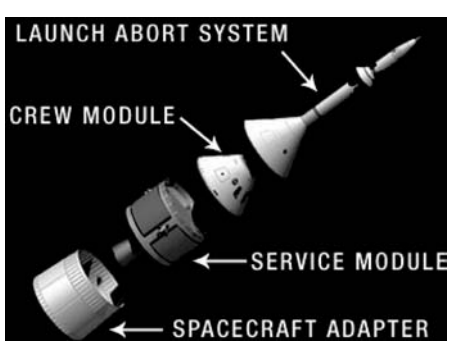

Fig. 2. Components of the Crew Exploration (Image courtesy of NASA).

Goddard Space Flight Center, Greenbelt, MD. Goddard has responsibility for communications, tracking and support mechanisms for the CEV. The center will also continue its work on the Lunar Reconnaissance Orbiter mission, set to launch in October 2008. See also http://www.nasa.gov/centers/goddard/home/index.html.

Jet Propulsion Laboratory, Pasadena, CA. JPL leads a multi-center activity in support of the Mission Operations Project to plan systems engineering processes related to operations development and preparation. JPL also provides co-leadership for the Constellation Program Office Systems Engineering and Integration Software and Avionics team. See also http://www.nasa.gov/centers/jpl/home/index.html.

Johnson Space Center, Houston, TX. Johnson, home to NASA's astronaut corps and mission control, is managing the Constellation Program. The center will integrate the CEV, Crew Launch and Cargo Launch Vehicles for all mission operations. JSC is the lead for the crew module, and will provide flight operations support to the Crew Launch Vehicle. As with Shuttle program and Apollo before, JSC will plan missions, train crews and run mission control. See also http://www.nasa.gov/centers/johnson/home/index.html.

Kennedy Space Center, FL. Kennedy will continue its tradition of launching NASA's explorers into space. See Figs. 3 and 4. KSC hosts the Ground Operations Project, which manages all activities related to ground operations for the launch and landing sites, including ground processing, launch, and recovery systems. See also http://www.nasa.gov/centers/kennedy/home/index.html.

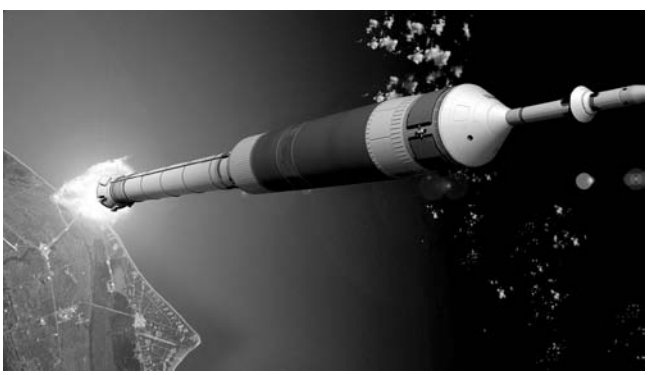

Fig. 3. The Crew Launch Vehicle. (Image courtesy of NASA/John Frassanito and Associates).

Fig. 4. Cargo Launch Vehicle. (Image courtesy of NASA/John Frassanito and Associates).

Langley Research Center, Hampton Roads, VA. Langley leads Launch Abort System integration supporting the CEV Project, providing oversight and independent analysis of the system's development. Langley also leads the Command Module Landing System Advanced Development Project and will support CEV testing. See also http://www.nasa.gov/centers/langley/home/index.html.

Marshall Space Flight Center, Huntsville, AL. Marshall hosts the Constellation Launch Vehicle projects, responsible for managing all Crew Launch and Cargo Launch Vehicle related activities. Marshall will design the Crew Launch Vehicle's first stage and is responsible for launch vehicle testing. See also http://www.nasa.gov/centers/marshall/home/index.html.

Stennis Space Center, MS. By building on more than 40 years of experience in rocket propulsion testing, Stennis will continue to serve in its traditional test role, serving as the integration lead for all propulsion testing. The first rocket engine to be tested will be the J-2X, an engine similar to those tested at the center 40 years ago for the Apollo Saturn V rockets. In the Constellation Program, the J-2X will be used to power the Upper Stage of the Crew Launch Vehicle. See also http://www.nasa.gov/centers/stennis/home/index.html.

The Engineering & Science Directorate (ESD) is the office responsible for overseeing the safe operation of one of a kind national test facilities valued at over $ 2 billion and for overseeing several rocket engine propulsion test programs such as Space Shuttle Main Engine acceptance testing and Ares 1 J-2X engine testing for NASA's next generation of rockets for Lunar and Mars exploration. The Directorate is also engaged in scientific research in support of NASA's Applied Sciences Program as well as various technology development initiatives.

Specifically, the directorate:

- Manages, develops, operates and maintains SSC's Rocket Propulsion Test capabilities, including world-class people, facilities, and associated processes and procedures.
- Accomplishes the development, flight certification, and acceptance testing of the Space Shuttle Main Engine.
- Works directly with the Rocket Propulsion Test Management Board (RPTMB) to provide test operations services to a variety of customers including NASA, DoD, commercial entities, and others, for the development of propulsion systems, engines, subsystems, and components.
- Conducts scientific research focusing on the use of remote sensing applications in coastal environments; supports scientific and engineering technology requirements through a series of technology development initiatives.

Stennis Space Center's Engineering & Science Directorate maintains full scale rocket engine/motor test facilities, component and small engine test facilities, and a materials test facility. Test facilities are comprised of two single position large scale engine test stands; one dual position large scale engine and stage test stand; and the E-Complex for testing of small engine and single/multiple components. Additional details can be found using links from this page. The Directorate also maintains scientific and engineering laboratory capabilities to support ocean color remote sensing, calibration/validation for coastal remote sensing and modeling products, algorithm development, and sensor development to support scientific and propulsion testing applications.

CONSTELLATIONS. In astronomy this term is used to designate certain groupings of the stars. From earliest recorded history we find that the larger star groups (constellations), the smaller groups (asterisms such as the Pleiades), and the individual stars have received names symbolizing meteorological, religious, or mythological beliefs. The idea that the constellation names and myths are of Greek origin has been quite completely disproved. It seems highly probable that they are of Semitic or Pre-Semitic origin and that they found their way into Greece through contact with the Phoenicians (sailors who used the stars constantly in their profession).

The oldest record of an actual constellation listing is found in the Creation Legend in about 650 B.C. This Legend was recorded on Cuneiform from even earlier records. From this time onward, frequent references to the constellation legends are to be found both in poetical and historical writings. The basis for the modern constellation division is to be found in the list of 48 constellations published by Ptolemy in about 150 A.D. This list is based upon the writings of Ptolemy's predecessors, notably Hipparchus.

Volans

The boundaries of Ptolemy's constellations were very indefinite, and many visible stars were left out entirely. Furthermore, his list only covered that portion of the heavens visible from the southern Mediterranean regions. In the 1,800 years since Ptolemy's time, the list has been added to and the boundaries defined, until, at present, all stars are included in some one of the constellations. The International Astronomical Union placed the matter of defining the constellation boundaries in the hands of a special committee, and in 1930, the final list was published.

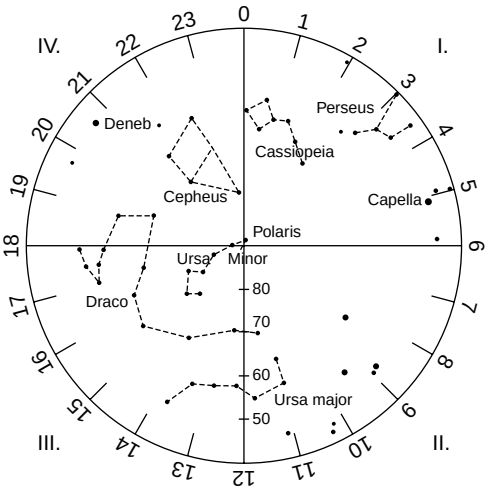

Fig. 1. Circumpolar stars.

Several attempts have been made to supplant the ancient mythological names with more modern ones (e.g., the Coelum Stellatum Christianum of Julius Schiller, in 1627, in which we find the ancient names replaced by names of various Church dignitaries), but none of the attempts has been successful.

The most important and easily recognized constellations will be found on the accompanying star maps (Figs. 1, 2, and 3); the numbers, e.g., Aries — Fig. 3 (2, N), refer to the particular map and the location on that map where the constellation will be found. The list accompanying 2 and 3 contains the names of all the constellations now used; those in bold-face type are treated elsewhere in this volume in special articles, and those marked with an asterisk are the original constellations of Ptolemy.

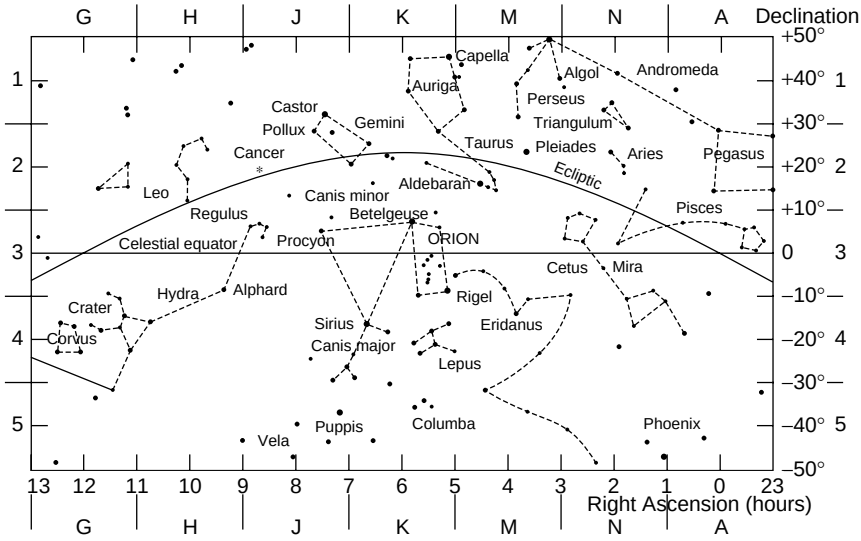

Fig. 3. Equatorial stars (continued).

CONSTIPATION. A sluggish action of the bowels, usually accompanied by difficulty in evacuation. Many persons have the idea that they are constipated, when actually they are not. As a result, they form the habit of taking laxatives and enemas, which cause irritable bowel symptoms. The concept that defecation should occur after a meal, or that copious evacuations are necessary, is unfounded, but many individuals are obsessed with notions that their bowels do not move frequently enough. A weakening of normal bowel function and the development of increasing instability in bowel habits almost always follow the habitual administration of laxative agents. The incidence of hemorrhoids is much greater in cathartic users than in other persons.

Constipation is a common complaint of peptic ulcer patients. Often, the constipation is regarded as the cause of the pain, with the result that the patient may take laxatives habitually. The resultant bowel upset may be severe.

In true constipation, the ease and sense of completeness of evacuation of the rectum and lower part of the colon is lacking. Constipation is more common among women than men. Habitual constipation occurs in young adults and becomes established in their twenties. Although practically half the population will give a history of constipation at some time, x-ray studies have shown that true constipation is not as frequent as imagined.

Many factors may be responsible for, or contribute to the production of constipation. Apart from obvious gross mechanical obstruction caused by tumor, adhesive bands, or strictures, constipation may be caused by habit, diet, or the state of the muscles of the bowel.

The act of defecating can be readily inhibited by an effort of the will, and a habit of refusing to respond to the urge to defecate is a common cause of constipation. The sensation of a full rectum usually occurs regularly at some definite time each day, and refusal to respond causes the desire to defecate to pass. The rectum becomes accustomed to the increased fecal bulk and there is retention of feces in the distal colon and rectum. This leads to excessive absorption of fluid; hence, the feces become dry, hard, and less easily expelled. As a result of continued overloading, the bowel musculature becomes sluggish in its action, and thinning and lack of tone may result. Properly regulated habits, rather than purgatives, are more likely to correct this type of constipation.

The diet may be responsible for constipation when it contains too little of undigestible residue, or roughage, which normally stimulates intestinal activity, or when the diet is not fluid enough. The times at which meals are taken are also important, because regular meals stimulate regular emptying of the large bowel.

Senility, obesity, lesions of the central nervous system, and generalized disease may rob intestinal muscles of their normal reactivity so that the propulsive mechanism of the bowel may not function efficiently. A diet low in calcium, potassium, or vitamin B, also may cause this condition.

A segment of the large bowel may be the site of muscular spasm and cause only spasmodic contractions, which have little value in moving the feces onward. Such a contracted bowel may be felt through the abdominal wall as a thick cord. This type of spasm may be caused by disease of the gallbladder, duodenum, or appendix, or it may be the result of overwork, worry, or shock.

Certain individuals are born with abnormally long colons and this condition may be accompanied by constipation. Passage of material is naturally slower through a greater length of bowel and there is more opportunity for fluid absorption. Individuals with this congenital abnormality may have the desire to defecate only once or twice a week. Distention of the elongated bowel occurs, and pressure on other parts of the bowel, bladder, or blood vessels results.

Constipation is usually relieved by adequate amounts of laxative foods in the diet. Foods which stimulate bowel action are fats, fruits, vegetables, and coarse cereals. Fruits contain a high proportion of undigestible cellulose, as well as sugars, acids, and salts, which have a chemically stimulating effect on the bowel. Undigested fat supplies a mild lubrication to the feces, while partially digested fats are mildly irritating and activate the bowels.

See also **Colitis and Other Inflammatory Bowel Diseases**; and **Diarrhea**. See also the section “Role of Fiber in Diet” in the entry on **Diet**.

CONSTITUENT. 1. In general, one of the elements or parts of a compound. 2. An identifiable component in the microstructure of an alloy. It may be a phase or a characteristic configuration of several phases.

CONSTRAINT. Any particle or collection of particles is said to be subject to constraint if the number of degrees of freedom is less than $3N$, where N is the number of particles. Specifically, constraint is the property that distinguishes a mechanism from other mechanical linkages. A mechanism has constrained motion in that a motion of one part is followed by a predetermined motion of the remainder of the mechanism. To determine whether a mechanical linkage is a mechanism or not, Klein advocated applying the criterion of constraint, defined as follows:

$$J = \frac{3N - 4 + \gamma - P}{2}$$

in which J is the number of joints in the mechanism, N is the number of links in the mechanism, γ is the number of independent prismatic chains, that is, those whose joints are of the sliding type, P is the number of point or line type of contact joints in the mechanism. When this equation yields an identity, the mechanism is said to be constrained for all dimensions.

CONTACT ANGLE. A term applied to the angle formed by a liquid on the surface of a solid at the gas-solid-liquid interface, measured as the dihedral angle in the liquid. Its value depends on the relative surface energies of the three interfaces, vapor-solid, vapor-liquid and solid-liquid.

CONTACT LENSES. Contact lenses are thin, finely crafted plastic discs designed to fit over the cornea of the eye, usually to correct vision problems caused by refractive error. They are held in place by

a natural layer of tears on the surface of the eye. In addition to their obvious cosmetic advantages over eyeglasses, contact lenses provide better peripheral vision and virtually eliminate the image distortion sometimes caused by eyeglasses. Contact lenses are now available for the correction of most vision problems caused by refractive defects of the eye including nearsightedness, farsightedness, astigmatism, and presbyopia.

Contact lenses were first described and sketched by Leonardo da Vinci in the early 1500s, and the first workable model — a 1/4-inch-long glass tube filled with water and containing a microscopic lens — was developed and used by Thomas Young in 1801. In 1887, a German glassblower produced the first see-through eye covering. In 1888, two European researchers simultaneously reported using contact lenses to correct optical defects.

In 1929, Hungarian physician Dr. Joseph Dallos perfected a method of making molds from living eyes. This enabled the manufacture of lenses that, for the first time, conformed to the actual shape of the eye. William Feinbloom, a New York optometrist, made the first American contact lens and also introduced the use of plastic to the manufacturing process. Contact lenses were made an official part of the practice of optometry in 1945 when the American Optometric Association formally recognized contact lens fitting as an integral part of their profession.

The first soft contact lenses were developed in 1960, but were not generally available to the public until 1971. Toric lenses for astigmatism were approved in 1978 and the first rigid gas permeable (RGP) lenses became available in 1979. The next decade saw many advances including the introduction of tinted lenses, bifocal lenses, daily wear soft lenses, disposable lenses, and extended wear RGP lenses. The 1990s saw more advances including disposable tinted lenses, daily disposable lenses, and the first disposable lenses that included protection against ultraviolet sunrays.

Contact lenses are generally categorized as "hard" lenses or "soft" lenses. As the name implies, hard contact lenses are manufactured from a rigid material, poly(methyl methacrylate) (PMMA). PMMA is a tough, clear material that was the original plastic used in the development of contact lenses. In modern hard lenses, PMMA is often combined with other plastics to increase the oxygen permeability. These are called rigid gas permeable (RGP) lenses. Soft contact lenses are made from a plastic hydrogel polymer, hydroxyethyl methacrylate (HEMA) and have a high water content.

In addition to being categorized as either "hard" or "soft," contact lenses may also be identified by their "wearing" characteristics (extended wear, daily wear, disposable, etc.) and according to the type of prescription (toric, aspheric, bifocal, etc.). The following descriptions are those generally used by the ophthalmic community in describing the various types of contacts lenses.

Daily wear soft lenses. These lenses are made of flexible, soft plastics that to allow oxygen pass through to the eye. They are easy to get used to and comfortable to wear. Because they fit close to the eye and are more difficult to dislodge, they are often recommended for sports. They will not work to correct all vision problems and may not provide the sharp vision required by some wearers. They also require daily removal and cleaning.

Disposable soft lenses. Disposable soft lenses are normally worn for one or two weeks and then discarded. They are easy to get used to and comfortable to wear. Because they fit close to the eye and are more difficult to dislodge, they are often recommended for sports. They will not work to correct all vision problems and may not provide the sharp vision required by some wearers. They also require daily removal and cleaning, but they require less cleaning than daily wear soft lenses.

Daily wear disposable soft lenses. This type of lens is designed to be worn for a single day, discarded at night, and replaced by a new pair in the morning. The big advantages are that no lens care is needed and a fresh pair of lenses is worn every day.

Planned replacement soft lenses. These contact lenses are replaced on a planned schedule, usually every two weeks, monthly, or quarterly. They are available for most prescriptions and require minimal care because they are frequently replaced.

Extended-wear lenses. Either soft or RGP lenses, these can usually be worn for up to seven days without removal. Because of the continuous wear, more frequent visits to the eye doctor for follow-up care may be required.

Daily wear rigid gas permeable (RGP) lenses. RGP lenses are manufactured from slightly flexible plastics that allow oxygen to pass through. These lenses may provide sharper vision than soft lenses and can be used to correct most vision problems. They are also more durable and easier to care for, but often require a longer adaptation period.

Spherical contact lenses. Soft or hard contact lens that contain a single prescription power.

Aspheric contact lenses. Premium contact lenses for borderline astigmatic patientsand for those who are just beginning to develop presbyopia.

Toric contact lenses. Soft or hard contact lenses that contain both a spherical and cylinder component to correct prescriptions that have astigmatism. These lenses may be thicker in one area than another in order to maintain correct orientation on the eye.

Bifocal contact lenses. Like bifocal eyeglasses, bifocal contact lenses are designed to provide sharp vision up close and at a distance. Several different designs are available depending on the specific needs and adaptability of the patient.

Monovision contact lenses. A term sometimes used in a special contact lens fitting technique that is an alternative to bifocal contacts. Using this technique, the eye doctor fits a near vision contact for reading in one eye and a distance vision contact in the other. The technique is very effective for some patients, but does require some adaptation and sometimes results in compromised depth perception.

Vision Rx, Inc., Elmsford, NY

CONTACT POTENTIAL DIFFERENCE. In his experiments with electroscopes, Volta found that when pieces of two different metals, otherwise insulated, are brought into contact, they acquire opposite charges and maintain a difference of electrical potential even while still touching. This potential difference he found to be characteristic of the given pair of metals. Thus when the metals are iron and copper, the iron has a potential about 0.15 volt higher than the copper, while for tin and iron the difference is 0.31 volt, tin being the higher. Volta listed a series of several metals, viz., zinc, lead, tin, iron, copper, silver, gold, such that when any two are put in contact, the one first named is at the higher potential. "Volta's law," which he was not in a position to demonstrate but which was established much later, states that the potential difference between any two metals in direct contact is the sum of the potential differences between intervening metals of the series. Thus for tin and copper (above) it is 0.31 volt + 0.15 volt = 0.46 volt; and it makes no difference whether the tin and copper are in direct contact or have other metals intervening between them.

The contact potential difference depends on the relative Fermi levels of the two solids. On contact, electron flow will take place until the Fermi levels of the two solids are equal. This will result in a potential difference between the two solids, called the contact potential.

A distinction must be made between the contact potentials in air and the so-called "intrinsic" contact potentials in a vacuum with all adsorbed gases removed. According to Millikan, the intrinsic potential difference between two metals A and B is expressed by $V_{AB} = h(v_A - v_B)/e$, in which h is Planck's constant, v_A and v_B are the critical frequencies of photoelectric emission for the two metals (see **Photoelectric Effect**), and e is the electronic charge. In any case, if the electronic work functions of the metals are p_A and p_B, the contact potential difference is $V_{AB} = (p_A - p_B)/e$. The work functions, and hence V_{AB}, are in general dependent upon the medium surrounding the metals. Accurate measurements of these potentials are, unfortunately, very difficult.

CONTAGION. The communication of disease by direct or indirect contact between a patient or carrier and a susceptible subject. Diseases so transferred are frequently termed *communicable diseases*.

It is mandatory in the United States that the following diseases be reported to local health authorities and to the Centers for Disease Control (Atlanta, Georgia) on a weekly basis: acquired immunodeficiency syndrome (AIDS), amebiasis, anthrax, aseptic meningitis, botulism (infantile botulism reported separately), brucellosis, chickenpox, cholera, diphtheria, hepatitis A, hepatitis B, hepatitis (unspecified), legionellosis, leprosy, leptospirosis, malaria, measles (rubeola), meningococcal infections (civilian and military separately), mumps, pertussis (whooping cough), plague, poliomyelitis, psittacosis, rabies (human), rheumatic fever (acute), rubella (German measles), rubella congenital syndrome, salmonellosis (except

typhoid fever), shigellosis, syphilis (primary and secondary), tetanus, trichinosis, tularemia, typhoid fever, and typhus fever (flea-borne and tick-borne reported separately).
This responsibility rests with physicians and hospitals.

CONTINENTAL DRIFT. The idea that the continents are not fixed in place, but capable of shifting around the Earth's surface, is an old one. As soon as decent maps of the world became available, several scholars noticed that the Atlantic coasts of Africa and South America were a good match, suggesting that these two continents once fitted together. But it was not until the twentieth century that the idea of continental drift went from a wild notion to the prevailing orthodoxy among geologists.

In 1915, the German meteorologist Alfred Wegener published the first detailed work which argued that continents had moved through time. His ideas were ridiculed by geologists, because no one could imagine the continents ploughing through the oceanic crust without leaving huge crumpled mountains built from the ocean floor in front of them. However, some southern hemisphere (especially South African) geologists were advocates of continental drift. They pointed to the peculiar distribution of distinctive Permo-Triassic plants (such as the seed fern *Glossopteris*) and animals (the aquatic reptile *Mesosaurus*, the synapsids *Lystrosaurus* and *Cynognathus*) as evidence for the former existence of a southern continent called *Gondwanaland* (or Gondwana), consisting of Africa, South America, India, Australia, Antarctica and Madagascar. They also pointed to three distinct late Palaeozoic floral provinces: a southern flora, dominated by *Glossopteris*, found on most of the Gondwana continents, which were at temperate and polar latitudes; a northern flora found in the great coal swamps of the late Carboniferous, which was dominated by lycopsids (scale trees and club mosses) and located in the ancient tropics; and a third, distinctive Asiatic floral province. These provinces are oddly scattered on a modern map of the world, but if they were placed in their late Palaeozoic continental positions, all the Gondwana fragments (Africa, South America, India, Australia, Antarctica) would come together, as would the northern continents to form a supercontinent known as Laurasia (North America plus western Eurasia). In the Pennsylvanian (late Carboniferous), the fragments of Asia had not yet collided with Siberia, but in the Permian this collision formed a single global continent called Pangaea. See also **Wegener, Alfred Lothar (1880–1930)**.

Current Evidence

The continental drift hypothesis was scorned by northern hemisphere geologists until the late 1950s and 1960s, when new evidence emerged from the sea floor and from geophysics. Ancient magnetic directions recorded in rocks around the world showed their continents had moved long distances with respect to the Earth's magnetic poles. Oceanographic surveys showed that there was an immense range of mountains (the longest and highest in the world) which ran down the middle of the Atlantic, and also in the middle of the Pacific and Indian oceans. These mid-ocean ridges turned out to be the sites where the Earth's crust pulls apart in a process called sea floor spreading. In addition, at the edges of some continents, there were long chains of volcanoes and regions of high seismic activity, such as the 'ring of fire' around the Pacific. Geophysical data showed that in these regions, one continent is plunging underneath another in a process called subduction. The friction between the overriding and downgoing slabs produces earthquakes, and the melting of the downgoing slab as it plunges into the hot mantle produces the chain of volcanoes above each subduction zone. See also **Ocean**.

By the mid-1960s, geology had undergone a scientific revolution in its understanding of the Earth, known as plate tectonics. The Earth's crust is broken up into more than twenty distinct tectonic plates which move around and slide over the mantle, and pull away or collide with one another as they do so. Where they separate, new oceanic crust is formed by sea floor spreading; where they collide, crust is consumed in subduction zones. However, if two colliding plates are made of granitic continental crust, which is buoyant and will not subduct, then there is a massive collision, producing crumpled, thrust-faulted mountain ranges such as the Himalayas or the Alps. In a few places, the plates are neither spreading nor colliding, but sliding past one another in what are known as transform faults. These great fault zones, such as the San Andreas fault of California, generate enormous friction and huge earthquakes as two plates grind past one another.

Since then, geologists have found further evidence of how continents move today, and in the past. Using laser range-finding from satellites, it is actually possible to detect the motion of continents across the Earth's surface. In addition, the motions of earthquakes have shown that the Earth's crustal plates are moving with respect to one another at the rate of centimeters (inches) per year. The latest geophysical data from seismic imaging of the mantle has allowed geologists to see the underlying currents that drive the motions of the crustal plates. Certain fixed 'hot spots' on the mantle are responsible for periodically punching upward through the overlying plate as it moves past, producing chains of volcanoes. These include the Hawaiian–Emperor seamount chain, which is currently erupting Kilauea volcano on the main island of Hawaii, but in the past formed the older Hawaiian Islands and the submerged seamount chain that runs beneath the Emperor Islands, and stretches over 1,000 km (621 miles) to the west of Hawaii. Another 'hot spot' lies under Yellowstone National Park in Wyoming, but during the last 15 million years it burned a trail from the Columbia River basalt eruptions of eastern Washington and Oregon, to the Snake River Plain of southern Idaho, to its present position. Such 'hot spot tracks' allow us to determine absolute plate motions with respect to fixed positions on the mantle, and further understand how plates move.

Past Plate Motions

In the thirty years since the plate tectonic revolution, many scientists have reconstructed detailed maps showing the ancient distribution of continents. For the last 200 million years, the present continents have been moving apart as they split away from the global supercontinent of Pangaea. In the late Triassic and Jurassic, North America separated from Pangaea, causing the opening of the North Atlantic. In the Cretaceous, South America and Africa split open along the South Atlantic, and both separated from Antarctica–Australia. Also in the Cretaceous, India broke away from the southern continents and raced across the Indian Ocean, ploughing into southern Asia in the early Eocene to form the Himalayas. Australia did not separate from Antarctica until the late Eocene, and is now beginning to collide with Asia. Since the Cretaceous, a great tropical Tethyan seaway ran from the Mediterranean to Indonesia. It was fragmented when India collided with Asia, and Africa began its collision with Eurasia to form the Alps, and the collision zone between the Arabian peninsula and Iran.

Prior to the Permian supercontinent, a number of different plate configurations were found in the Palaeozoic. The Gondwanaland supercontinent existed for at least 800 million years. However, the northern continents jostled around in a variety of configurations during the Palaeozoic. For example, North America was located in the tropics and rotated by 90° during the Cambrian. By the Devonian, North America had collided with Europe to form the Caledonian–Acadian mountains. In the Pennsylvanian, southern North America began to collide with the African and South American portions of Gondwanaland, causing the Appalachian mountain belt. In the Permian, Siberia collided with Europe, crumpling up the Ural mountains between them.

Prior to the Palaeozoic, the positions of the continents are more controversial, since the evidence is difficult to interpret. Most geologists agree that about 700 million years ago, there was another supercontinent, known as Rodinia, which placed western North America adjacent to Antarctica, and fragments of Africa and South America adjacent to eastern North America and Europe; Siberia abutted Greenland. However, there are many other interpretations of how these late Proterozoic continents were assembled, and so far no reconstruction is supported by all the evidence. Plate reconstructions prior to 700 million years ago are much more speculative, since the evidence is so poor.

The motions of continents are important in explaining past geographic puzzles, but they also had climatic and oceanographic effects that were equally important. For example, the circum-Antarctic current presently circulates around Antarctica in a clockwise fashion, locking the cold air and water in around the South Pole. Consequently, there is little mixing of tropical and temperate water with the cold Antarctic waters, enhancing not only the refrigeration of the South Pole, but also the extremes between poles and equator. But in the Eocene, Antarctica was still connected to both South America and Australia, and there was no connection of the South Atlantic, South Pacific, and Indian oceans. Instead, each of these oceans was much warmer and milder because tropical and temperate waters mixed

with those of the polar regions. When Australia broke away in the late Eocene, and South America in the late Oligocene, the circum-Antarctic current formed and the Antarctic has been refrigerated ever since. This current was ultimately responsible for the global cooling that has occurred in the last 50 million years. See also **Earth Tectonics and Earthquakes**; and **Palaeoclimatology**.

Summary

Since the 1960s, geology has undergone a scientific revolution, where the old notion of continental drift has been revived as the modern theory of plate tectonics. This theory postulates that the Earth's crust is divided up into 20 or more tectonic plates, which shift with respect to one another, and with respect to the underlying mantle and core. Where two plates separate, new sea floor is created along mid-ocean ridges. Where two plates collide, one goes under another in a subduction zone, or the two plates smash together to form mountains. If the two plates slide past another, they form a giant strike-slip fault known as a transform. The concept of plate tectonics has radically changed not only the way geologists view the Earth, but also our understanding of historical biogeography.

CONTINENTALITY. In climatology, the degree to which a point on the earth's surface is in all respects subject to the influence of a landmass; the opposite of oceanicity (or oceanity). Continentality usually refers to climate and its immediate consequences. Usually, it is measured by the range of temperature, either the daily range or the difference between the average temperatures of the warmest and coldest months. Since the latter increases with the latitude, a convenient measure is the annual range of temperature divided by the sine of the latitude. In another form, the difference between January and July mean temperatures at a station is divided by the difference between the January and July means for the whole circle of latitude. An index of continentality, or coefficient of continentality, k, has been formulated by V. Conrad as follows:

$$k = \frac{1.7A}{\sin(\phi + 10^\circ)} - 14,$$

where A is the difference between the mean temperature (°C (32°F) of the warmest and coldest months and φ is the latitude of the place in question.

AMS

CONTINENTAL RISE. At the outer edges of the continental slopes, the slope lessens and decreases in degree of slope as the ocean floor is approached. The rise ranges in width from one to several hundred miles and may reach depths of 17,000 feet (5,180 meters) (approximately) where it is in contact with the floor of the ocean basin.

CONTINENTAL SHELVES. That portion of the ocean basin that fringes the continents in widths varying between a few miles and more than 200 miles (320 kilometers). They are generally very smooth, have gently sloping floors, averaging only a few feet per mile increase in depth so that at their outer edge they may be between 300 and 600 feet (90 and 180 meters) in depth with an average depth of 400 feet (120 meters). At this edge, the slope increases markedly and this is called the continental slope.

Epicontinental seas are shallow bodies of water deeper than continental shelves and having somewhat greater relief. They generally are somewhat greater than 600 feet (180 meters) in depth. Also termed epicontinental marginal seas.

Further information on the geology and composition of the continental shelves will be found in the entry on **Ocean**.

CONTINENTAL SLOPES. That part of the ocean basin found at the rims of the continental shelves. The slope is greater than the latter, averaging 3 to 6 degrees. The slope drops rapidly from depths of 300 to 600 feet (90 to 180 meters) to between 10,000–12,000 feet (3,000–3,600 meters) where the slope decreases and is replaced by the continental rise.

CONTINGENCY TABLE. The members of an aggregate may be classified according to qualitative or quantitative characteristics. Where the characteristics are qualitative a classification according to two of them may be set out in a two-way table known as a contingency table. For example, if the characteristic A is p-fold and a characteristic B is q-fold then the contingency table will be one of p rows and q columns. A given cell contains the number of individuals having both characteristics corresponding to A_j and B_k.

A *contingency coefficient* is a measure of the relationship between the two qualities as exhibited by the contingency table.

CONTINUITY (Equation). In one form of the equation of continuity, the principle of the conservation of matter is stated in the following form: The rate of increase of the particles in an element of volume is equal to the net inward flow across the surfaces of the element, i.e., the negative of the divergence. In mathematical terms,

$$\frac{d\rho}{dt} + \text{div } \mathbf{j} = 0$$

where ρ is the density of the medium and $\mathbf{j}$ is the mass current density vector. With proper changes in the meaning of ρ and $\mathbf{j}$, the equation expresses the conservation of other quantities, such as charge and energy.

For a fluid of constant density, conservation of mass requires that the flow field satisfies

$$\text{div } \mathbf{v} = \nabla \cdot \mathbf{v} = 0$$

in the Eulerian specification of the flow. The flow is *solenoidal*.

CONTINUITY OF STATE. This term is applied to a transition between two states, as between the gaseous and liquid states, in either direction, without discontinuity, or abrupt change in physical properties. Although this transition is not realizable in practice by mere pressure-volume change, it can be accomplished by some processes, as by a sequence of temperature changes in one direction at constant volume, followed by temperature changes in the other direction at constant pressure, or vice versa.

CONTINUOUS FUNCTION. A function of one variable $f(x)$ is continuous at a value $x = c$ when $f(c)$ has a definite value that is equal to the limit of $f(x)$ when $x \to c$. A function is continuous within an interval (a, b) when it is continuous at every point of the interval; at the end points it is sufficient that

$$\lim_{n \to a^+} f(x) = f(a); \lim_{a \to b^-} f(x) = f(b)$$

For the meaning of these symbols, see also **Limit**.

A function has a discontinuity or is discontinuous where it is not continuous. The usual type of discontinuity is a point at which the function becomes infinite, or where it has a finite jump (also called a saltus).

Important properties of a continuous function are: (1) if it is continuous in a closed interval (a, b), then among the different values of $f(x)$ in this interval, there is a greatest value M and a least value m; (2) if its interval of continuity is again (a, b), then between every two values x_1 and x_2 and

of x in this interval, $f(x)$ takes at least once every value between and $f(x_1)$ and $f(x_2)$.

A function of two variables, $f(x, y)$, is continuous at a point (a, b) if

$$\lim_{\substack{n\to a \\ n\to b}} f(x, y) = f(a, b)$$

CONTINUOUS VARIABLE. A continuous variable is one that may have any value within the range of variation. Examples are the weights of objects, the ages of people, and so on. A variable that is not continuous is said to be discrete or discontinuous.

CONTINUOUS-WAVE RADAR. A general species of radar transmitting continuous waves, either modulated or unmodulated. The simplest form transmits a single frequency and detects only moving targets by the Doppler effect. This type of radar determines direction, but usually not range. Also called *CW radar*. Two advantages of CW radar are the narrow bandwidth and low power required. Range information may be obtained by some form of modulation, e.g., frequency modulation, pulse modulation. See also **Doppler Effect**.

CONTOUR. A smooth curve composed of arcs bound together continuously, each arc having a common tangent. A closed contour may be decomposed into a series of closed smooth curves having no singular points. If the closed contour is traversed in a counterclockwise direction with respect to some point in the domain, the sense of the contour is positive.

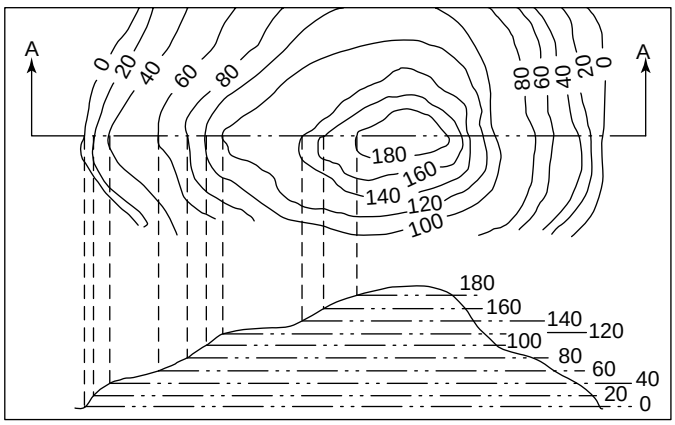

Fig. 1. Contours.

Integration along a closed contour C is indicated by the symbols $\int_C$ or $\oint$ and the result is a contour integral.

In the calculus of residues, the Bromwich contour is often useful. It extends from $c - i\infty$ to $c + i\infty$ where c is real and positive and the path so chosen that all singular points of the complex function are to the left of it.

In surveying terms, a contour is a means by which the three dimensions necessary to represent a point in space can be shown on a map. These three variables are: length, measured north and south; length, measured east and west; and height, above some arbitrary reference plane. On a topographical map height is shown by contours. See also **Topographical Mapping**. All points on a given contour line will be at the same elevation. Figure 1 shows the relation between height of a small irregular hill, and the corresponding contour lines as drawn upon a map. Occasionally special maps, instead of showing elevation as the third variable, give line of constant magnetic variation. See also **Compass (Navigation)**. These lines are called isogonic lines and the map is known as an isogonic chart.

While the contour line has its greatest use in land surveying and mapping, there are other technical uses. For example, the efficiency of a centrifugal pump varies both with the pumping head and with the discharge. Accordingly, centrifugal pump characteristics are often given with the efficiency displayed as contour lines upon a head-discharge plane.

CONTRACTILE VACUOLE. A vacuole within the cytoplasm of many freshwater protozoans, and a few metazoans, that collects and expels excess water from the cell. In most species of *Paramecium* there are two contractile vacuoles. These can be seen in living forms under the microscope. They gradually expand and then suddenly contract as the water is forced from the cell. Water is constantly being taken into these cells by osmosis and along with food. Without the functioning of contractile vacuoles excess water would accumulate in the cell.

CONTRACTILITY AND CONTRACTILE PROTEINS. The fundamental property of living matter on which its power of movement depends is termed contractility. In the simplest forms of living things, it is evident in the flowing movement of the material of the cell. In more complex forms, the property is centralized in muscle tissues. Muscle cells are elongate and are so arranged that necessary movements result from their shortening when stimulated.

The study of the fibrillar proteins of muscle invites interest for two reasons. On the one hand, they form the prime ingredients of the mechanism that performs a typical vital activity, movement, in its most specialized form; thus, the elucidation of their functions, and of the physical and chemical properties basic to it, represents one of the cardinal parts of molecular biology. On the other hand, the isolated proteins display such striking physical behavior that to the macromolecular physicist they are among the most fascinating materials. Unfortunately, they are difficult to obtain and exceedingly changeable and labile; thus, working with them is somewhat difficult.

The major fibrous proteins are myosin and actin. Other proteins that may be involved in myofibrillar structure are tropomyosin and paramyosin. All four proteins share certain chemical properties; among others, they are all exceptionally rich in ionizing amino acids, thus they are highly charged molecules. Myosin is an adenosine triphosphatase. The molecular weight is not accurately known; a number of determinations cluster around 500,000. Light scattering dissymmetry suggests a mean molecular length of about 1600 micrometers, and electron microscopy suggests similar lengths.

See also **Muscle**.

CONTRAST (Statistics). A contrast between a set of independent observations x_i of equal accuracy is a linear function $\Lambda = \sum \lambda_i x_i$ in which the sum of the coefficients $\sum \lambda_i = 0$. If σ^2 is the variance of a single observation and Λ, Λ' are two contrasts with coefficients λ_i, λ_i', then the variance of Λ is $\sum \lambda_i^2$ and the covariance of Λ and Λ' is $\sum \lambda_i, \lambda_i'$. If $\sum \lambda_i \cdot \lambda_i' = 0$, the contrasts are said to be orthogonal.

CONTROL ACTION. Of a controller or a controlling system, the nature of the change of the output effected by the input. The output may be a signal or the value of a manipulated variable. The input may be the control loop feedback signal when the setpoint is constant, an actuating error signal, or the output of another controller.

Adaptive. Control action whereby automatic means are used to change the type or influence (or both) of control parameters in such a way as to improve the performance of the control system.

Cascade. Control action where the output of one controller is the setpoint for another controller.

Derivative (Rate). Control action in which the output is proportional to the rate of change of the input.

Direct Digital. Control action in which control is performed by a digital device, which establishes the signal to the final controlling element.

Examples of possible digital (D) and analog (A) combinations for this definition are:

	Feedback Elements	Controller	Final Controlling Element
1.	D	D	D
2.	A	D	D
3.	A	D	A
4.	D	D	A

Feedback. Control action in which a measured variable is compared to its desired value to produce an actuating error signal that is acted upon in such a way as to reduce the magnitude of the error.

Feedforward. Control action in which information concerning one or more conditions that can disturb the controlled variable is converted into corrective action to minimize deviations of the controlled variable.

Feedforward control action can be combined with other types of control to anticipate and minimize deviations of the controlled variable.

High Limiting. Control action in which the output never exceeds a predetermined high limit value.

Integral (Reset). Control action in which the output is proportional to the time integral of the input, i.e., the rate of change of output is proportional to the input. See Fig. 1.

In the practical embodiment of integral control action, the relation between output and input, neglecting high frequency terms, is given by

$$\frac{Y}{X} = \pm \frac{I/s}{bI/s + 1}, \text{ where } 0 \leq b \ll 1$$

and

b = reciprocal of static gain

$I/2\pi$ = gain crossover frequency in cycles per unit time

s = complex variable

X = input transform

Y = output transform

I = integral action rate

Low Limiting. Control action in which the output is never less than a predetermined low limit value.

Optimizing. Control action that automatically seeks and maintains the most advantageous value of a specified variable, rather than maintaining it at one set value.

Proportional. Control action in which there is a continuous linear relation between the output and the input.

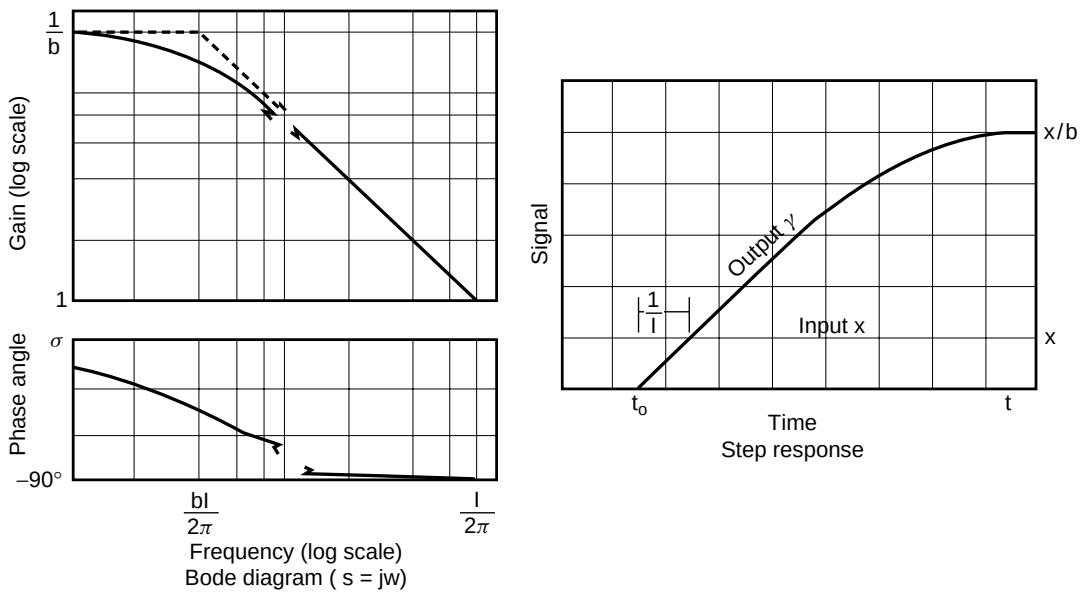

Fig. 1. Integral control action.

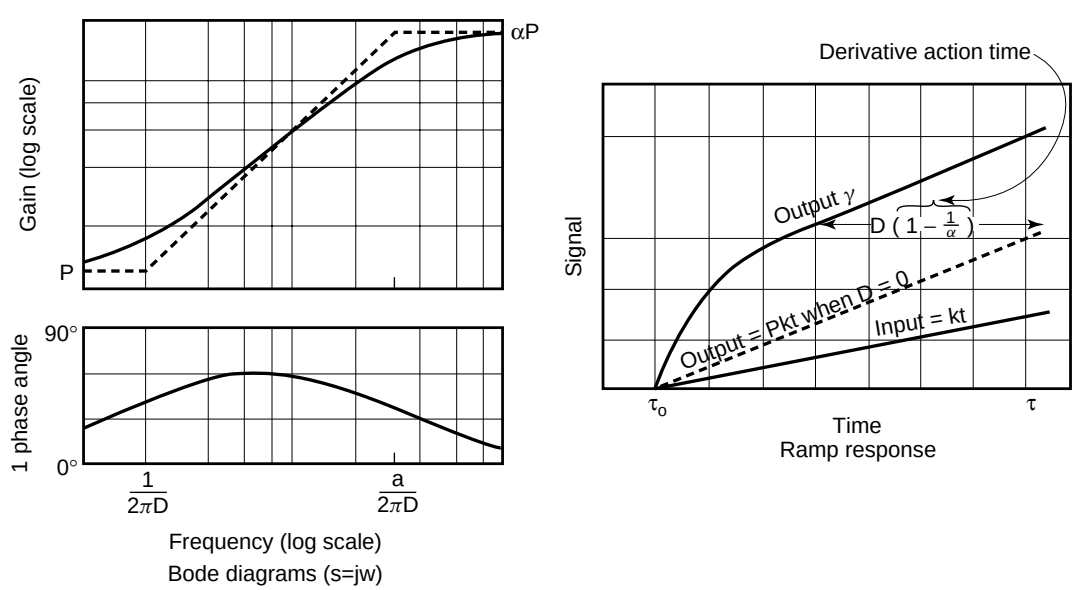

Fig. 2. Proportional-plus-derivative control action.

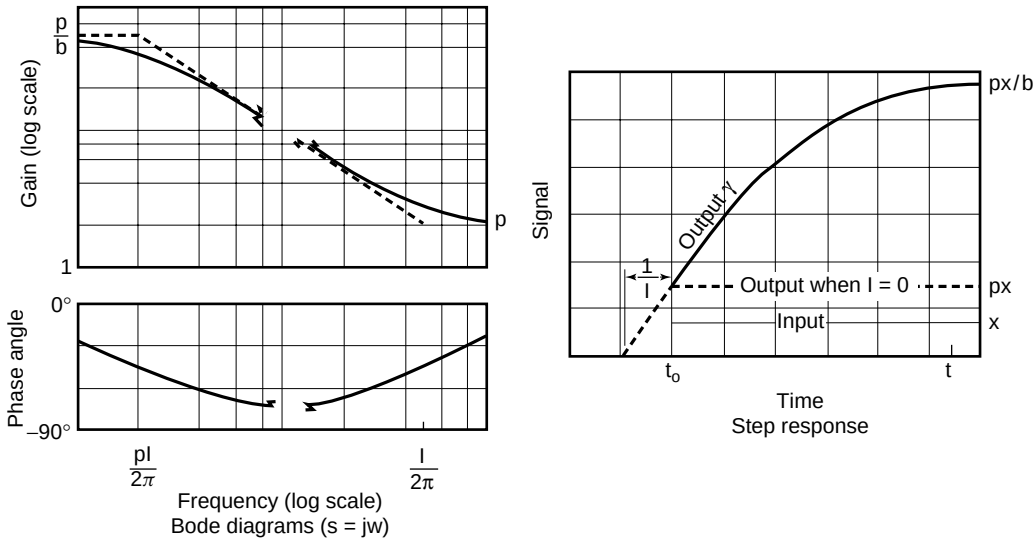

Fig. 3. Proportional-plus-integral control action.

This condition applies when both the output and input are within their normal operating ranges and when operation is at a frequency below a limiting value.

Proportional plus Derivative (Rate). Control action in which the output is proportional to a linear combination of the input and the time rate-of-change of input. See Fig. 2.

In the practical embodiment of proportional-plus-derivative control action, the relationship between output and input, neglecting high frequency terms, is given by

$$\frac{Y}{X} = \pm P\frac{1+sD}{1+sD/a}, \text{ where } a > 1$$

and

a = derivative action gain

D = derivative action time constant

P = proportional gain

s = complex variable

X = input transform

Y = output transform

Proportional plus Integral (Reset). Control action in which the output is proportional to a linear combination of the input and the time integral of the input. See Fig. 3.

In the practical embodiment of proportional-plus-integral control action, the relation between output and input, neglecting high frequency terms, is given by

$$\frac{Y}{X} = \pm P\frac{I/s+1}{bI/s+1}, \text{ where } 0 \le b \ll 1$$

and

b = proportional gain/static gain

I = integral action rate

P = proportional gain

s = complex variable

X = input transform

Y = output transform

Proportional plus Integral (Reset) plus Derivative (Rate). Control action in which the output is proportional to a linear combination of the input, the time integral of input and the time rate-of-change of input. See Fig. 4.

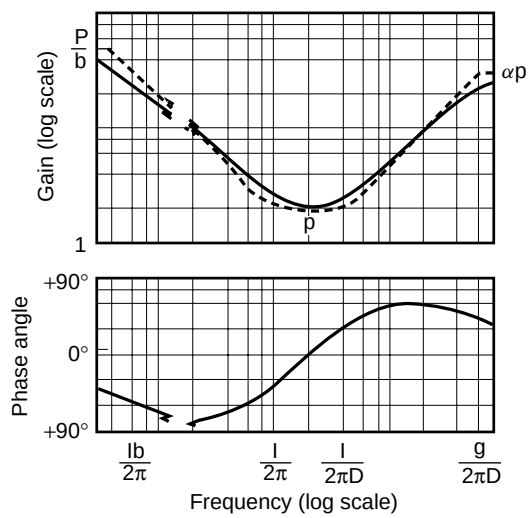

Fig. 4. Proportional-plus-integral-plus-derivative control action.

In the practical embodiment of proportional-plus-integral-plus-derivative control action, the relationship of output to input, neglecting high frequency terms, is given by

$$\frac{Y}{X} = \pm\ P\frac{I/s+1+Ds}{bI/s+1+Ds/a}, \text{ where } a > 1, 0 \le b \ll 1$$

Shared Time. Control action in which one controller divides its computation or control time among several control loops rather than acting on all loops simultaneously.

Supervisory. Control action in which the control loops operate independently subject to intermittent corrective action, e.g., setpoint changes from an external source.

Velocity Limiting. Control action in which the rate of change of a specified variable will not exceed a predetermined limit.

For a fundamental description of automatic control, see **Control System**.

Each process or machine to be controlled requires individual analysis prior to firmly specifying the desired control action. However, certain generalities can be helpful and these are summarized in Tables 1 and 2.

CONTROL CHART (Statistical Quality Control). A graphical device used to show the results of small scale repeated sampling of a manufacturing process. It usually consists of a central horizontal line corresponding to the average value of the quantitative characteristic under investigation together with upper and lower limits between which a stated proportion of the sample statistics should fall. Any marked divergence above or below

TABLE 1. CONTROL ACTION VERSUS PROCESS CHARACTERISTICS

Number of Process Capacities	Load Changes		Process Reaction Rate	Process Lag Times		Appropriate Control Action
	Size	Speed		Resistance-capacity	Dead Time	
Single	Any	Any	Slow	Moderate to large	Small	Two position. Two position with differential gap
	Moderate	Slow				Multiposition. Time proportioning
Single (self-regulating)	Any	Slow	Fast	Small	Small	Floating actions: Single speed; multispeed
		Moderate				Integral
Multiple	Small	Moderate	Slow to moderate	Moderate	Small	Proportional
Multiple	Small	Any	Moderate	Any	Small	Proportional plus derivative
Multiple	Large	Slow to moderate	Any	Any	Small to moderate	Proportional plus integral
Multiple	Large	Fast	Any	Any	Small	Proportional plus integral plus derivative
Any	Any	Any	Faster than that of the control system	Small or nearly zero	Small to moderate	Wideband proportional plus fast integral

TABLE 2. CONTROL ACTION VERSUS PROCESS TYPES

Process Type	Gain (Proportional)	Integral Control Action	Derivative Control Action
Flow and liquid pressure	0.2–50 (500–2% PB)	Necessary	Not necessary
Gas pressure	20-∞ (5–0% PB)	Not necessary	Not necessary
Liquid level	2–20 (50–5% PB)	Occasionally needed	Not necessary
Temperature	1–10 (100–10% PB)	Necessary	Necessary

Note: PB = Proportional Band.

these control limits will tend to indicate that new causes are at work beyond those responsible for the random variations inherent in large scale production. A set of points outside the control limits will signal the need for special inquiries for the purpose of identifying the new factor(s) at work. The two lines are known as *upper and lower control limits*.

CONTROLLER (Automatic). A device which operates automatically to regulate a controlled variable, such as temperature, pressure, flow, liquid level, viscosity, etc. in the process industries, or speed, dimension, and motion of machines.

The major types of controllers include:

Direct Acting. A controller in which the absolute value of the output signal increases as the absolute value of the input (measured variable) increases.

Floating. A controller in which the rate of change of the output is a continuous (or at least a piecewise continuous) function of the actuating error signal.

The output of the controller can remain at any value in its operating range when the actuating error signal is zero and constant. Hence the output is said to float. When the controller has integral control action only, the mode of control has been called "proportional speed floating." The use of the term integral control action is recommended as a replacement for "proportional speed floating control."

Integral (Reset). A controller that produces integral control action only. This type of controller also may be referred to as a proportional speed floating controller.

Multiple-speed Floating. A floating controller in which the output may change at two or more rates, each rate corresponding to a definite range of values of the actuating error signal.

Multiposition.. A controller having two or more discrete values of output. See Fig. 1.

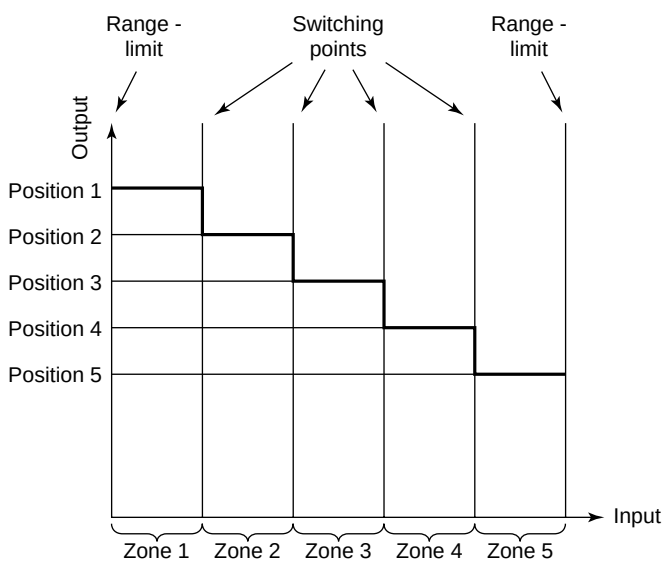

Fig. 1. Multiposition controller.

On-off. A multiposition controller having two discrete values of output, fully on, or fully off. See Figs. 2 and 4.

Proportional. A controller that produces proportional control action only.

Proportional plus Derivative (Rate). A controller that produces proportional plus derivative (rate) control action.

Proportional plus Integral (Rate). A controller that produces portional plus integral (reset) control action.

Proportional plus Integral (Reset) plus Derivative (Rate). A controller that produces proportional plus integral (reset) plus derivative (rate) action.

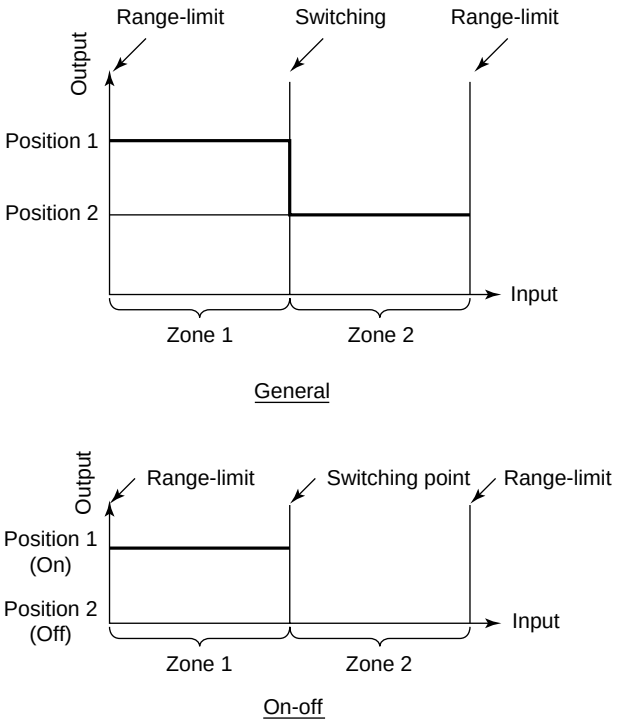

Fig. 2. Two-position controller.

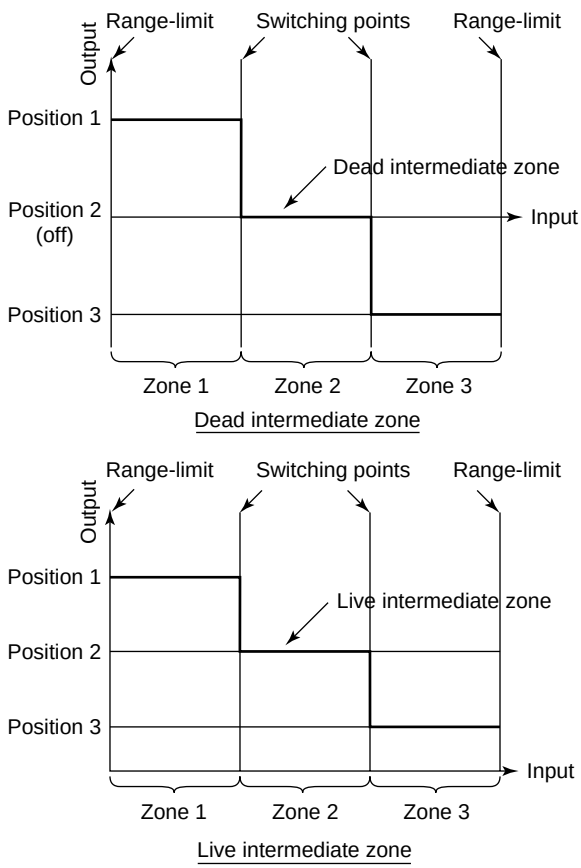

Fig. 3. Three-position controller.

Ratio. A controller that maintains a predetermined ratio between two or more variables.

Reverse Acting. A controller in which the absolute value of the output signal decreases as the absolute value of the input (measured variable) increases.

Sampling. A controller using intermittently observed values of a signal such as the setpoint signal, the actuating error signal, or the signal representing the controlled variable to effect control again.

Self-operated (Regulator). A controller in which all the energy to operate the final controlling element is derived from the controlled system, through the sensing element.

Single-speed Floating. A controller in which the output changes at a fixed rate increasing or decreasing depending on the sign of the actuating error signal.

A neutral zone of values of the actuating error signal in which no action occurs may be used.

Three Position. A multiposition controller having three discrete values of output. See Fig. 3.

This is commonly achieved by selectively energizing a multiplicity of circuits (outputs) to establish three discrete positions of the final control element.

Time Proportioning. A controller whose output consists of periodic pulses whose duration is varied to relate, in some prescribed manner, the time average of the output to the actuating error signal.

Time Schedule. A controller in which the setpoint (or reference input signal) automatically adheres to a predetermined time schedule.

Two Position. A multiposition controller having two discrete values of output. See Figs. 2 and 4.

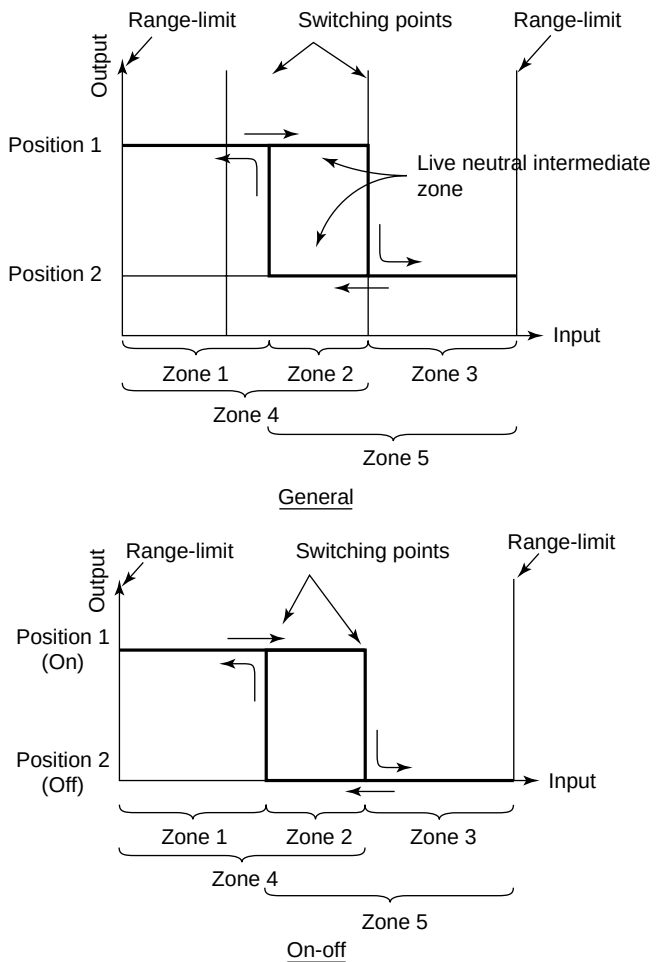

Fig. 4. Two-position controller with neutral intermediate zone.

The control actions mentioned in the foregoing definitions are described under **Control Action**. For a fundamental description of automatic control, see also **Control System**. A consolidated list of references is given at the end of the latter article.

CONTROL SYSTEM. A system in which deliberate guidance, with a minimum assistance of human intervention, is used to achieve a prescribed value of a variable (temperature, pressure, flow, etc.) or group of variables. An automatic control system may be very simple, such as the thermostatic regulation of a refrigerator, oven, or living space, to the full coordination of a complex manufacturing process. Automatic control systems are widely used in the process industries (so-called wet processes), in which variables are controlled — as in an alkylation or catalytic cracking process found in a petroleum refinery; or in the manufacture of pulp for paper from wood feedstocks; or in the automatic batching, mixing, and melting of ingredients for making glass and other ceramics. Automatic control systems are also widely used in the discrete-piece manufacturing industries, as encountered in the automated machine shop, in engine assembly, and in the packaging of foods and other products. Automatic control systems find common application in all types of power-generating facilities — hydroelectric, geothermal, conventional fossil-fuel steam plants, solar and nuclear power facilities. Automatic control systems are also found in numerous aspects of transportation, ranging from autopilots for aircraft and automated navigation systems for ships and missile guidance to simpler applications as found in automotive electronic systems.

To explain the fundamentals of automatic control systems, the example used here is that which generally applies to the control of a process and for ease of comprehension, the hardware depicted is essentially of the analog (rather than digital) type. Control fundamentals apply to either analog or digital control systems, but to most persons it is easier to visualize the operation of an analog system — and then translate this understanding to digital modes.

A control system, for purposes of definition, can be subdivided into two systems: (1) a *controlling system*; and (2) a *controlled system*. With reference to Fig. 1, these and other definitions are described in the following paragraphs.

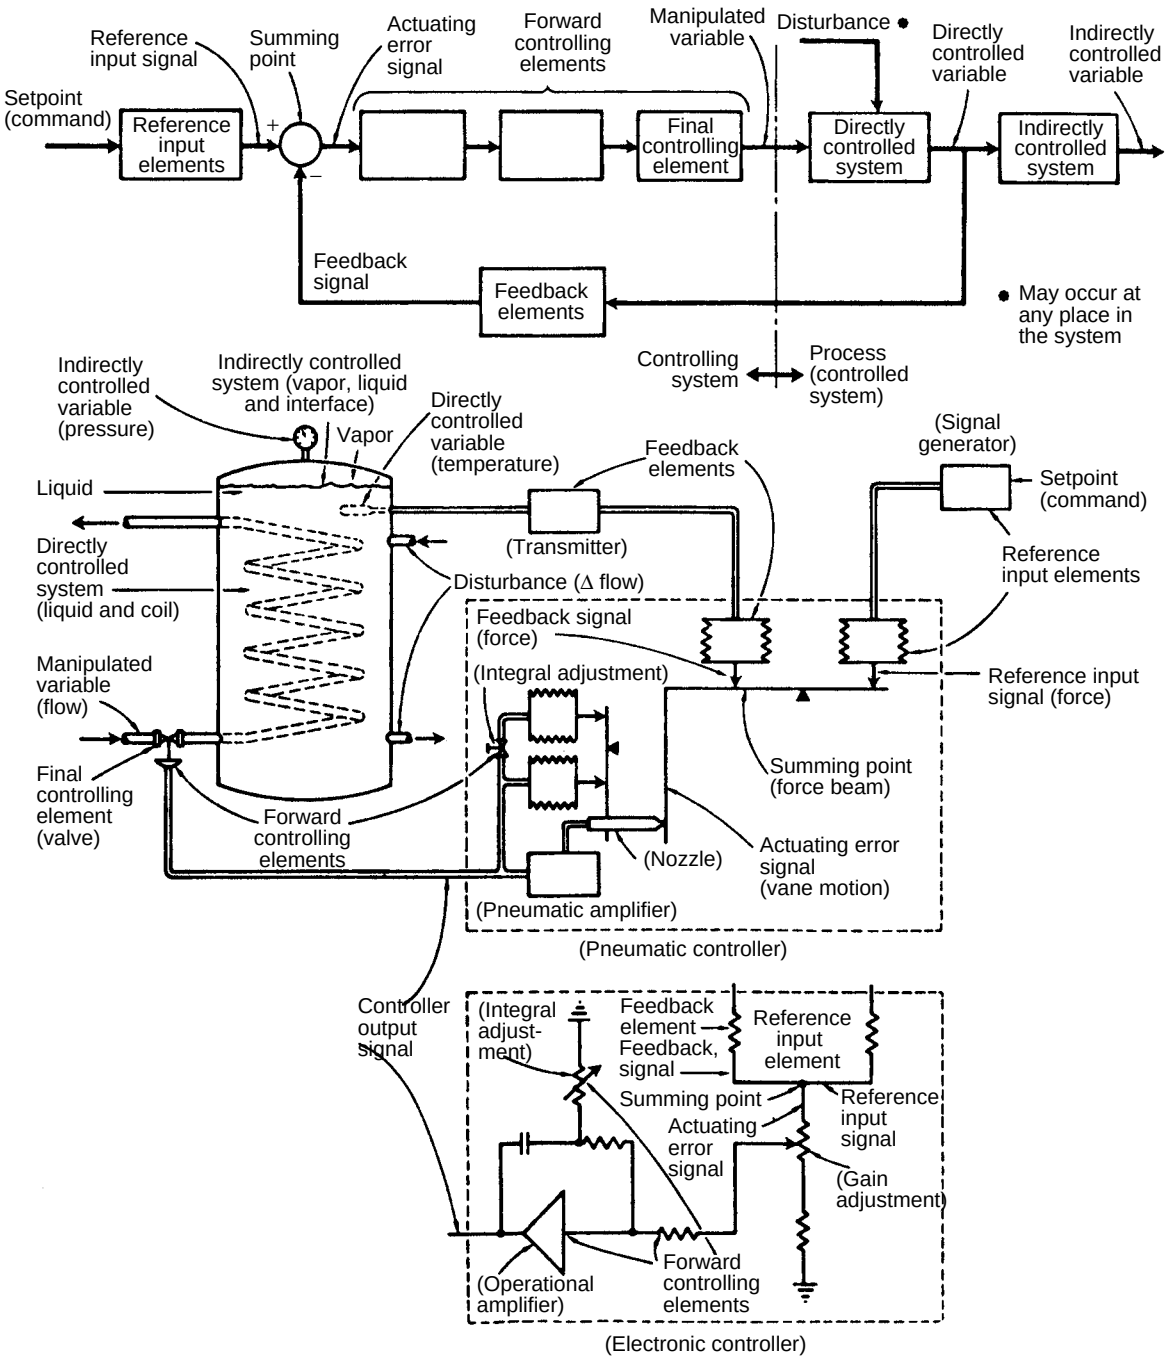

Fig. 1. Representative automatic control system, indicating major elements and terminology. For ease of comprehension, analog hardware is featured in this example. It should be stressed, however, that digital hardware has displaced and continues to displace much of the analog hardware formerly used.

Controlling System. 1. Of a *feedback control system*, that portion which compares functions of a directly controlled variable and a setpoint and adjusts a manipulated variable as a function of the difference. It includes the reference input elements, summing point, forward and final controlling elements, and feedback elements (including sensing element). 2 Of an automatic control system *without feedback*, that portion of the control system which manipulates the controlled system.

Controlled System (or Process). The collective functions performed in and by the equipment in which the variable(s) is (are) to be controlled. Equipment as embodied in this definition should be understood not to include any automatic control equipment. The terms *process* and *controlled system* are interchangeable.

Variable (Directly Controlled). In a control loop, that variable whose value is sensed to originate a feedback signal.

Variable (Indirectly Controlled). A variable that does not originate a feedback signal, but which is related to and influenced by the directly controlled variable.

As shown by Fig. 1, the directly controlled variable is the temperature of the fluid in the tank. An indirectly controlled variable is the vapor pressure above the level of the fluid in the tank.

There are numerous variables that may be controlled, depending upon the process involved. A process need not be a process in the normal sense, i.e., a heating, cooling, or reacting process, but for the purposes of definition here also includes machines whose operation is dependent upon the manipulation and control of variables. Variables include: temperature (as in the example of Fig. 1); pressure; the level of liquids (as in tanks, reactors, and other process vessels); the level of bulk solids (as in bins and silos); the flow of a liquid or gas in a pipeline; the flow of a bulk solid (as on a conveyor); the density or specific gravity of liquids and gases; the viscosity of fluids; the moisture content of materials; the chemical composition of materials; and several other variables, the control of which affects such factors as final product quality, yield, and safety. Some typical process operations in which control is important include drying, distilling, absorbing, adsorbing, centrifuging, filtering, heating/cooling, compressing, electroplating, reacting, power generation, and dozens of others.

Variable (Manipulated). A quantity or condition that is varied as a function of the actuating error signal, so as to change the value of the directly controlled variable. In any practical control system, there may be more than one manipulated variable. Accordingly, when using the term, it is necessary to state which manipulated variable is being discussed. In process control work, the one immediately preceding the directly controlled system is usually intended.

With reference to Fig. 1, the temperature of the fluid in the tank (the directly controlled variable) is held at a steady value by adjusting (manipulating) the flow of steam to the heating coil of the tank. The flow of steam is thus the manipulated variable.

Feedback Control Action. This is a control action in which a measured variable is compared to its desired value to produce an actuating error signal, which is acted upon in such a way as to reduce the magnitude of the error.

Measured Variable The physical quantity, property, or condition that is measured. Sometimes this is referred to as the measurand. In the example of Fig. 1, the measured variable is the temperature of the fluid in the tank. In this case, it is the same as the directly controlled variable.

Desired Value. The value of the controlled variable wanted or chosen. In the example of Fig. 1, the desired value refers to the temperature of the water desired in the tank.

Signal. Information about a variable that can be transmitted. In the example, this is information pertaining to the temperature of the water in the tank.

Measured Signal. The electrical, mechanical, pneumatic, or other variable applied to the input of a device. It is the analog of the measured variable produced by a transducer (when such is used).

In the case of a filled-system thermometer for measuring temperature, as shown in Fig. 1 measuring the tank temperature, the change of temperature surrounding the sensitive thermometer bulb causes a change in the pressure within the filled system, an increasing temperature causing a greater internal system pressure and vice versa for a decreasing temperature. This pressure is constantly detected, measured, and compared by the thermometer instrument. Thus, the measured signal in this instance is pressure.

In the case of a thermocouple-type thermometer, the measured signal is an emf, which is the electrical analog of the temperature applied to the thermocouple. In the case of a flowmeter, the measured signal may be a differential pressure, which is the analog of the rate of flow through an orifice. In an electric tachometer system, the measured signal may be a voltage that is the electrical analog of the speed of rotation of the part coupled to the tachometer generator. In all of these examples, transducers are involved.

Transducer. An element or device that receives information in the form of one physical quantity and converts it to information in the form of the same or some other physical quantity. Types of transducers include a primary element, a signal transducer, and a transmitter.

Primary Element. The system element that quantitatively converts measured variable energy into a form suitable for measurement. In the example of Fig. 1, the thermometer bulb is the primary element.

Signal Transducer. Also called signal converter, a transducer that converts one standardized transmission signal to another, as in the case of converting from pneumatic to equivalent electric signals and vice versa.

Transmitter. A transducer that responds to a measured variable by means of a sensing element, and converts it to a standardized transmission signal that is a function only of the measurement. It will be noted from Fig. 1 that the measured signal (pressure in the thermometer system) goes directly to a transmitter. Here that signal is converted into a pneumatic signal, lying within a range of 3 to 15 psi (0.44 to 2.18 kPa).

Input Signal. A signal applied to a device, element or system.

Return Signal. In a closed loop, the signal resulting from a particular input signal, and transmitted by the loop and to be subtracted from the input signal.

Error Signal. In a closed loop, the signal resulting from subtracting a particular return signal from its corresponding input signal.

Actuating Error Signal. The reference-input signal minus the feedback signal.

Reference-Input Signal One external to a control loop which serves as the standard of comparison for the directly controlled variable.

Closed Loop. Also termed *feedback loop*, a signal path that includes a forward path, a feedback path, and a summing point, and forms a closed circuit.

Summing Point. Any point at which signals are added algebraically.

Setpoint *(Command)* An input variable which sets the desired value of the controlled variable. The input variable may be manually set, automatically set, or programmed. It is expressed in the same units as the controlled variable.

Returning to Fig. 1 and relating the foregoing terms to the illustration, note that the setpoint (either manually set or remotely set by a program) causes an input signal to the system to be generated. In essence, the signal generator translates a dial setting into a corresponding quantitative electrical or pneumatic signal. In this case, a pneumatic signal is shown. After this translation, the command is termed a reference input signal and through an appropriate bellows element in this case, the signal takes the form of a force. The previously mentioned transmitter generates a like, but not necessarily an equal, signal (feedback signal), which also through a matched bellows takes the form of a force. In this example, a force beam serves to algebraically compare the two signals and in this case the force beam becomes the summing point. If the two signals are perfectly equal, no action occurs, indicating that the temperature of the fluid in the tank is at exactly the value commanded by the setpoint. When the signals are not equal, the balance assumes an unbalanced condition in one direction or other, depending upon whether the temperature of the fluid in the tank is above or below the setpoint temperature.

In the case of the instrument shown, by way of a movable vane stationary nozzle configuration, the difference between the feedback signal and the reference input signal (called the actuating error signal) causes motion of the vane and via a pneumatic amplifier creates the controller output signal which causes the final controlling element (a valve in this example) to

become more fully open or more fully closed, as may be required to bring the temperature back into line.

Final Control Element. That element in the controlling system that changes a variable in response to the actuating error signal, synonymous in the example of Fig. 1 to the controller output signal. The valve shown in this case is a pneumatically actuated diaphragm motor valve. In the case of an electric controller, the steam valve may be a motor-operated valve, or an electropneumatic operator, which will take an electric signal and convert it for operation of a diaphragm valve. There are many possible hardware configurations.

Disturbance. An undesired change in a variable applied to a system that tends to affect adversely the value of a controlled variable. In the example, one form of disturbance could be a greater or lesser drawoff of heated fluid from the tank because of varying needs for the fluid at point of use. Or, the pressure in the steam supply line could change, altering the Btu content of the steam. If the tank were located outside, ambient conditions could change. In the long-term, the coil could scale up, thus affecting heat-transfer efficiency. In other words, there are numerous factors that motivate against maintenance of a steady state of the system. If this were not the case, an automatic control system hardly could be justified.

Because the system has capacity, an adjustment of the steam supply valve will not be immediately sensed by the thermometer bulb and hence a warming or cooling trend will not be corrected instantaneously.

Dead Time. The interval of time between initiation of an input change or stimulus and the start of the resulting response. This is illustrated in Fig. 2. Dead time also is referred to as *distance-velocity lag or transportation lag*. Terms included in Fig. 2 are defined as follows:

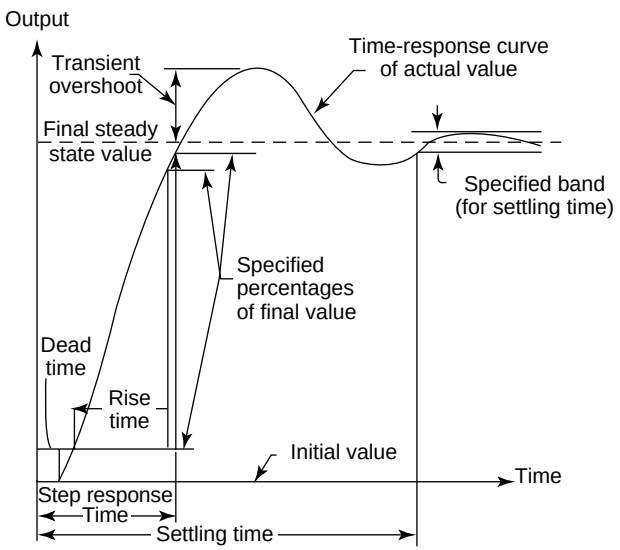

Fig. 2. Typical time response of a system to a step increase of input.

Rise Time. The time required for the output of a system (other than first order) to make the change from a small specified percentage (often 5 to 10) of the steady-state increment to a large specified percentage (often 90 to 95), either before or in the absence of overshoot. If the term is unqualified, response to a unit step stimulus is understood, otherwise the pattern and magnitude of the stimulus should be specified.

Step Response Time. Of a system or an element, the time required for an output to make the change from an initial value to a large specified percentage of the final steady-state value either before or in the absence of overshoot, as a result of a step change to the input. Usually stated for 90, 95, or 99% change.

Settling Time. The time required, following the initiation of a specified stimulus to a system, for the output to enter and remain within a specified narrow band centered on its steady-state value. The stimulus may be a step impulse, ramp parabola, or sinusoid. For a step or impulse, the band is often specified as ±2%. For nonlinear behavior, both magnitude and pattern of the stimulus should be specified.

Depending upon the nature of the process and, in particular, the manner and speed with which a process responds to change and correction, the type of automatic control system best suited may range from a simple on-off controller to a proportional plus integral (reset) plus derivative (rate) controller. The cost of the control system versus the desired control results often is a tradeoff. However, it usually is best to err on the side of the more sophisticated control, because even a fraction of a percentage increase in product quality or yield, multiplied by the many thousands of days the control system probably will be in use, can justify the very best control system for a given situation.

The numerous types of control actions available are defined under **Control Action**. In addition to matching the control action with the needs of the process, the type of control medium must be selected. Generally, these are of the following categories: (1) *pneumatic*, in which air pressure values comprise the control system signals, (2) *electric*, in which either millivolts or milliamps are the control system signals, and (3) *hydraulic*, usually used where powerful final controlling elements are required. Conversion of signals from one medium to the next — pneumatic to electric, electric to pneumatic, electric to hydraulic, and even double conversions, such as pneumatic to electric back to pneumatic, or electric to pneumatic and back to electric, are rather commonly encountered in control system technology. The task of selecting control system equipment is further complicated by the rather wide variety of primary elements obtainable. For example, just for the measurement of temperature, there are thermocouples, various forms of radiation and optical pyrometers, resistance thermometers, filled-system thermometers (used in the example of Fig. 1), bimetallic thermometers, and so on. However, because of the vast variety of requirements posed by thousands of different processes (and machines), it is fortunate that such a wide variety of hardware is available.

Human Factors in Control System Design. For a long period extending from the 1930s through the mid-1950s, the control room of a large manufacturing facility featured large instruments (indicators and recorders, many of which were equipped with control-adjusting means) mounted on long panels. Such panels were usually sectionalized to make it effective and convenient for two or more operators to monitor and adjust a series of related instruments. In the much earlier days of process instrumentation (prior to World War II), the majority of instruments were locally mounted out on the process so to speak, with few, if any, of the measurements transmitted to a central control room. Developments in both the fields of pneumatic and electric transmission of measurement data made it possible to put nearly all of the instruments in a central control facility. This greatly improved coordination of the process, but did introduce much additional expenditure in transmission tubing or wiring. As processes became more complex, requiring many more variables to be measured and controlled, the control rooms and instrument panels in them became exceedingly large.

As a partial answer to this problem, indicating, recording, and controlling instruments were miniaturized. This trend, of course, greatly increased the information display density on a control panel, which on the one hand, made it more physically convenient for the operators, but on the other hand, tended to contribute to operator confusion; thus there was introduced a much greater attention to the human engineering factors involved in the operator/process or machine interface. So-called graphic instrument panels were introduced in the early 1950s, in which the smaller (miniaturized) instruments were grouped on the panel within a diagram of the process or machine being controlled. This approach improved the immediate identification of measurement data with a given part of the process. In the 1960s and continuing to the present era, the use of cathode ray tube (CRT) displays has been stressed. The CRT, for example, ties in very well with measurement data in digital input formats. Further, the CRT screen can be time-shared among numerous variables. The use of the CRT increased at a rapid pace as the control systems proper became more and more digitalized, with the introduction not only of central computers, but of minicomputers, miniprocessors, and the like.

Instrumentation and automatic control professionals have become increasingly concerned with the operator/process interface. These activities have been spurred by the thorough analysis of this problem in connection with the handling of emergency situations.

Control System Infrastructure. Advancements in data processing and computer technology have created many new and interesting options for the control system engineer, of which *distributed instrumentation and control* is a major component. The organization of a control system is frequently

referred to as *control system architecture*, a topic covered in some detail in the article on **Control System Architecture**.

CONTROL SYSTEM ARCHITECTURE. The functionality and architectures of control systems have been evolving steadily for many years. Advances in semiconductor technology have allowed far more processing power to be applied at all levels of plant control than was believed possible only a few years ago. This power will be needed to achieve plantwide automatic control, including full integration of process control and plant business systems, over the years ahead.

Control System Hierarchy. Process plant control often has been described as a hierarchy or layering of functions. Four major layers, starting from the bottom up, are shown in Fig. 1.

Direct Process Control. Four elements are considered here: (1) *Regulatory control*, i.e., closed-loop feedback systems for controlling variables, such as pressure, temperature, flow, etc. The fundamental building block of regulatory control is the PID (proportional, integral, derivative) control function. See also **Control Action**. To this can be added many other dynamic functions, such as *lead/lag* and *deadtime*, as well as calculations to accomplish control of difficult situations which often involve a number of measurements and final control elements. Regulatory control execution rates vary with the type of loop. (2) *Advanced (nonconventional) regulatory control*: This includes closed-loop control algorithms beyond the PID algorithm used for most loops, as well as feedforward, overrides, and Smith Predictor. Examples of these nonconventional forms include internal model control (IMC), inferential control, and dynamic matrix control (DMC). These approaches are usually based on process models and are used on processes that are not well regulated, such as those with intermittent observations (analytical measurements, for example), very significant pure delays (deadtime), and other difficult-to-handle behavior, such as inverse response. (3) Sequence control related to the logic control of equipment having discrete states, such as motor start/stop, valve open/close, etc. For complex processes, this can involve many devices which must function in the proper order for process startup, shutdown, and other situations. Response times of about ten milliseconds are typical. (4) *Sequence-of-events recording* to assist in problem solving. In upset situations, for example, it is highly desirable to know what events occurred, and in what order. Speed is critical inasmuch as events can occur within a few milliseconds of each other. Events must be time stamped, stored, and be readily available for expert analysis.

Process Monitoring. This level of the hierarchy (Fig. 1) involves five major factors: (1) *CRT operator stations*, which are used to interface the operator with the control system. From cathode ray tube (CRT) screens and keyboards, the operator can look at values of input data, manipulate the process setpoints and outputs, monitor alarms, and change process parameters. For batch processes, recipes may be called up from a master library and scheduled for execution by the system. CRTs can graphically display controller faceplates and process flowsheet graphics. The operator station also can recall stored data for trend and historical plots. (2) *Alarms*, need to inform the operator when a process variable goes into an alarm condition. The location of the problem and means for correcting the condition must be easily available and with means for the operator to correct the condition easily and rapidly. Operator comprehension of the alarm system cannot be overemphasized. (3) *Trending*, a procedure for plotting process variables versus time on CRT graphics, thus providing the operator with a useful tool for determining loop stability. Update times faster than once every five seconds are used where fast-responding loops are involved, such as in flow and pressure control. (4) *Graphics* are needed to convey information quickly and efficiently to the process operator. CRT graphics with considerable capability and flexibility are frequently provided at the operator station. Because many control systems are used as replacements to earlier panel-board controls, the CRT graphics nevertheless must mimic panel-board functions. (5) *Report generation* is the presentation of process data and should be determined by its usefulness. Reports should have access to as much information in the system as possible. Time of day and date should be available for key events. Arrangements of data or report formats must be easy to change so that reports can be custom-tailored to their users.

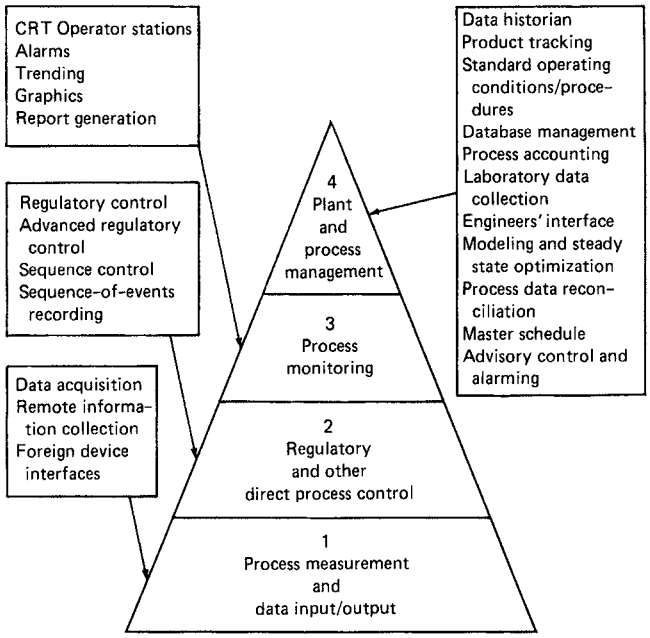

Fig. 1. Control system hierarchy. (1) At the process measurement and data I/O level is the myriad of sensors and actuators that allow a control system to function. (2) Regulatory control at the second level is the control of process parameters, such as flow, temperature, and numerous other variables. Also, at this level, is the first level of control logic used for equipment start/stop and cycling through simple operations. The combination of regulatory control and sequence control is termed direct process control. (3) At the third level, process monitoring includes the presentation of all the process-related data to the operators, giving them the ability to make changes as required. (4) At the highest level, process management includes a higher-level functionality, which will facilitate process diagnostic work, alter plant operating conditions for maximum profit, and schedule production based on demand for the product. It should be noted that this pyramidal concept of control not only includes those elements (sensors, measurement, decision making, actuation, and feedback) that make control of a process or machine possible, but includes numerous support functions, particularly the data display and analysis functions which assist both in the making of human as well as automatic decisions.

Process Management. Going to a further level in the hierarchy pyramid of Fig. 1, process management functions are related to the overall way a process is run. For example, these functions may adjust operating conditions to improve process yield or product quality. The loss of any of these functions will rarely lead to equipment shutdown because normal plant operation can usually continue for several hours without serious product degradation. However, over a significant time span, they are important. There are at least eleven important factors in connection with process management functions: (1) *Data historian* provides the

long-term storage and retrieval of all available process information with respect to time. (2) *Product tracking* is an extension of the data historian, allowing specific batch or lot identification to be associated with stored process parameters. This function is useful in connection with problems in a specific customer shipment, which can be compared with other production runs made under similar conditions. (3) *Standard operating conditions/procedures* — these are the target parameters required to manufacture a particular product. For a continuous process, they may be setpoints for various process variables. For a batch process, they are more complex and will include times and rates of change. Associated with these conditions are procedures (automatic and manual) for transitioning from one product to another. (4) *Database management* is particularly important when changes are made in plant equipment or procedures for manufacturing a product. Alterations beyond the routine operator changes in the control system may be involved. To minimize the disturbance to the manufacturing process, good database maintenance is essential. The system may have built-in protection against access by unauthorized personnel. Isolation between operating areas is also used to protect against inadvertent alteration of the wrong data. For continuous control loop strategies, a graphical self-documenting function is desirable. (5) *Process accounting* is concerned with the collection of total materials and energy consumption by the system and reported on an hourly, shift, weekly, calendar-month, and accounting-month basis. (6) *Laboratory data collection* involves the reporting of process samples that are analyzed in a laboratory (composition and physical properties — variables that sometimes cannot be determined on-line). The results of laboratory data are delayed by the time required to complete the analysis. (7) *Engineers' interface*. This can be used to make process data available to the engineer in a graphical format, enabling statistical analysis in the form of a library of statistical functions as well as providing high-level programming languages and tools. Historical plots may easily be expanded to show much detail, or condensed and contracted to provide a "big picture." (8) *Modeling and steady state optimization* are important functions for process management. Process models can be used to supplement unreliable measurements, compensate for slow or noisy laboratory analyses, enhance control strategies, and allow optimization of product quality, process energy consumption, and profit. Several modeling techniques are used, including steady state and dynamic first principle models, linear-dynamic models, and statistical steady state models. The choice of these depends upon the modeling function performed and the allowable computer time available. Steady state optimization is of particular interest and value. With this technique, model parameters are varied to find the set that yields the process optimum. Then, actual process operating conditions can be changed to these values for improving product quality, lowering energy consumption, and enhancing profit. Sophisticated search techniques, such as linear and nonlinear programming are usually used to change model parameters and find the optimal conditions with the least number of trials. (9) *Process data reconciliation* is a function that uses material and energy balance calculations in conjunction with statistical data analysis to detect process measurement problems and to improve the quality of process data. Sometimes, the approximate values of measurements are predicted mathematically while a measurement device is under repair. Similarly, errors in accounting reports are mathematically corrected for measurement errors. (10) *Master schedule* is a function that uses information on product inventory and anticipated demands so that a production schedule for a process unit or area can be created. Although this function is most common in connection with multistream batch processes, the approach also can be used for continuous processes to drive product transitions. (11) *Advisory control and alarming* is a method of process control that is used when corrective action is not well defined and when operator intervention is desirable. In advisory control, the digital computer is used to monitor the process, decide the most probable cause of a problem, and determine the best course of action to take. This information is then conveyed to the operator — to be combined with human insight into the operation of the process. The operator then will determine if (a) a change should be made manually, or (b) to allow the system to make needed changes automatically. This type of control has been in use for some time and may be a good candidate for the incorporation of advances in artificial intelligence (AI) as they develop (particularly expert systems).

All of the foregoing functions in the hierarchy of control affect the choice of control system architecture for a *given application*. These functions have played a major role in molding the control system architecture in use and available today. Figure 1 can serve as a convenient checklist of these functions. Other important factors that define system architecture are summarized in Table 1.

State-of-the-Art Control Systems

Steps in the evolution of current control systems are summarized in Table 2. In terms of contemporary control systems, principal attention is given here to those control system factors which have been greatly impacted by advances in electronics which have occurred at an exceedingly rapid rate during the past few years.

Data Highways. The communication highway is fundamental to the operation of a control system. Through it, the control functions may be physically separated from each other and from the operator's console. The highway is also important in establishing functional isolation. For this, multiple processors can be dedicated to the control and operator interface functions. This is essential to achieving high reliability inasmuch as it minimizes the impact of any single failure in the system. This also helps to prevent user-induced failures by keeping each processor within its loading limitations. Functional isolation also can be helpful in preventing the ripple effect common among single processor systems — where a change in one function can impact the operation of another, unrelated function.

Data highway communications must be able to handle heavy traffic loads and must be reliable. For example, response within one or two seconds is needed in reporting alarms to the operator, in displaying fast-moving process data for manual control, and in maintaining tight control where several controllers are involved. Loading requirements become more severe as system size increases. Communication speeds must be guaranteed even during abnormal operating conditions. During process upsets, for example, many alarm conditions may suddenly change and must be reported to the entire system quickly so that remedial action may be taken. Process startup and shutdown are other examples that cause heavy communications loads.

Because system dependence on data highway operation is increasing, there is a large need to maintain secure communications at all times. Besides immunity from internal effects, such as sudden (burst) load increases, highways (and control systems in general) must be able to withstand the power surges in an industrial plant and during electrical storms. The latter are particularly severe where data highways are run outside over long distances. Dual (redundant) data highways are commonly used to diminish the risk of communications loss should one cable be damaged. The two highways can be routed over different paths to minimize the possibility of both being subject to the same source of damage.

Microprocessor-Based Controllers. There are two classes of controllers available in distributed control systems (DCS) which are briefly described in Table 2. The two classes are: (1) the multiloop controller, and (2) the single-loop controller. The multiloop controller can use one or more microprocessors (MPUs) to accomplish the control function on several (usually no less than eight) modulating control loops. Each controller includes dedicated I/O modules to interface to process measurement and control equipment. The controller can accommodate analog (continuous I/O), discrete (digital), and other field I/O. In some cases, serial ASCII interfaces to "smart" field analyzers, weigh scales, among others, are provided. The controller also manages communications to and from the data highway. This communication is primarily to report process information to the operator's console, but also can include data transactions to and from other process controllers (peer-to-peer) as well as to historian and other higher-level modules, programmable controllers, and mainframe computers.

The control functions available in the multiloop controller are usually limited to those in the algorithm library. These include regulatory feedback control algorithms, dynamic function blocks, logic processing and sequencing blocks, and some calculating capability. The entire algorithm library is generally included in read-only memory (ROM) in each controller — whether or not all algorithms are used. This is done by the manufacturer by using re-entrant (subroutine) programming so that the user simply provides the changeable process data (e.g., scaling, alarm limits, and tuning) and the block linkages (the sources and destinations of data passed between blocks). This approach to data organization greatly decreases the user's potential for errors in generating the controller database and is well suited for easily implementing control strategy changes.

The single-loop controller is similar to the multiloop controller in both functionality and physical components. These controllers often can

TABLE 1. MAIN FACTORS THAT DETERMINE CONTROL SYSTEM ARCHITECTURE

RELIABILITY

Direct control functions require higher reliability than process management functions. In general, the downtime of a control system should be small with respect to the overall plant downtime. If a plant runs continuously for months, this should be reflected in the control system reliability. If a failure in the control system can have catastrophic effects, this must be reflected in control system design. Where the latter condition may exist, back-up systems (or even separate safety systems) may be indicated.

TIMING

The timing requirements of control functions range from a few milliseconds (sequence of events, interlocking) to several hours (optimization) . Control of process variables (flow, temperature, pressure, etc.) usually requires between 1 and 5 executions per second. Effective transfer of information between processors over data highways often requires more than a second. To achieve the speed requirements for functions faster than one second, it is desirable to execute the function within one module. Regulatory control loop timing requirements frequently can be met by keeping the base-level control functions and related I/Os in one controller. Higher levels of control may require data from other controllers. Usually this can be accomplished without degrading the control because of timing. However, reliability may decrease because more processors are involved, increasing the likelihood of a failure. The data highway must be operational in such cases for full control.

DATABASE CONFIGURATION

In the case of well-understood and common plant control functions, such as simple regulatory control, sequencing, and report generation. the database can be relatively simple, easy to use setup techniques that require little or no user programming. Fill/in-the-blanks or menu-driven selection techniques are available and require much less sophistication and training than the programming/software-related functions.

When a programming environment is provided, several user tools should be provided, including text editors and compilers which pinpoint errors and provide English language error messages.

It is desirable to separate these two working environments so that (a) system support can be accomplished with minimum-required expertise, and (b) the difficulty of exchanging data between the two environments will not increase.

PROTECTION, ISOLATION, SAFETY, AND SECURITY

The question may be asked, “How many and which control functions should be handled by a single processor?” This involves system reliability and ultimately can impact on the ease of implementation and support. Generally, direct control functions do not belong in an environment shared with process management functions. Doing so subjects the control functions to loading effects which can adversely impact their critical timing requirements. Direct control functions should be isolated.

CRT Operator stations should be used only for levels of regulatory control where timing is not critical. Regulatory control assigned to one processor should be limited so that timing can be guaranteed for all operating conditions and will not slip or vary with process upset or other abnormal operating conditions.

Control function isolation improves protection against errors made in changing the database inasmuch as problems induced within one processor’s executable database are normally limited to that processor. Maintenance and overall support are also simplified. By isolating functions, the impact of hard failures in a processor can be minimized.

GLOBAL (SYSTEMWIDE) ATTRIBUTES

Even though system functions may vary in terms of the reliability needed, timing, and sophistication of working environment, they must work together if they report in some fashion to a network, that is, are part of an integrated system, in such cases, an alarm limit, for example, should be made only once for that change to be complete for the entire system. Conventions for naming devices and components should be consistent throughout the system. All identification of a particular measurement should be similar throughout the system regardless of the level or working environment. For example, having a 12-character tag name in one area of the system and a numbering system for processors and inputs in another area is undesirable, especially if cross referencing must be done manually.

For simple systems with few control system functions, deciding on a system architecture is usually straightforward. For complex systems, the selection process can be difficult and present many tradeoffs.

The first step is to decide which functions are to be included in the system, followed by developing a “functional description.” This should be based on the need and potential benefit to the operating process. Although planning an architecture for continued growth is excellent practice, system design should avoid unnecessary functions and keep the system as simple as possible. Having an overview of the entire system is essential. Available space and environmental conditions and other constraining factors are also needed, against which candidate system architecture can be tested.

Additionally, some fundamental decisions must be made about the system architecture. Will a host computer be needed? Will a distributed control system (DCS) be used? Will programmable logic controllers be used? Will separate subsystems be used? Will maximum integration be sought?

If regulatory control with CRT operation stations is required, a DCS will probably be used. Sequencing operations may elect a programmable controller or it may be desired to include this functionality in the DCS. If process management functions are required, a host computer may also be needed. When a DCS and a host computer are both used, considerable overlap in functionality may exist. In these cases, functions must be assigned to a system based upon reliability requirements. speed of execution, relative cost, and ease of support.

AFTER ANALYSIS of the foregoing restraints and targets, the basic architecture best suited will largely have been selected.

acquire many analog and discrete inputs, but are usually limited to about four analog outputs and some correspondingly small number of discrete outputs. The number of components is considerably smaller than multiloop controllers and there is usually only one or two printed circuit boards.

Multiloop controllers offer advantages in system cost, communications, and packaging density. Because there are more shared components, multiloop controllers are less expensive to manufacture per control function. These cost advantages are passed on to the buyer and result in a lower hardware cost per loop. The cost saving in using multiloop versus single-loop controllers can be substantial in large (over 500 loops) applications. Communications for multiloop controllers also can be simpler where many process inputs must be used for a coordinated control strategy, or where one variable is used repeatedly by many control loops. This can occur in feedforward control or in advanced control strategies.

The use of multiloop controllers, however, is not without drawbacks. A single component failure can disable every loop within a given control-reason, they are available with redundant (backup) processors. In most cases, these will automatically take over in the event of a failure without any human intervention and with minimal disturbance to the process under control. In many cases, redundant (auxiliary) I/O is also available to minimize the risk of an I/O failure. Both processor and I/O redundancy may be provided as either one-on-one or one-on-several to allow some flexibility for varying process criticality. Single-loop controllers are also available with redundancy although this is not required for most applications.

CRT Operator Stations. The operator station provides the primary window to the process and to the performance of the controller modules. Each station has a keyboard and one or more CRTs for display. Although more than one CRT is usually desirable per operator, usually there are additional keyboards provided, with a usual ratio of one keyboard per CRT. A printer or other hard copy device also is provided for permanent records.

The operator station allows process information to be displayed, parameters to be changed, automatic control sequences to be run and, in most cases, the full system database to be maintained. The display of information has several formats.

A system overview display provides deviation and alarm information for a large number of points. From this, the appropriate group display

TABLE 2. PRINCIPAL STEPS IN EVOLUTION OF CONTROL SYSTEM ARCHITECTURE

ENTRY OF COMPUTERS INTO CONTROL SYSTEMS

As early as 1959, computers were introduced in a serious way for regulatory process control. A few years earlier, computers were used to monitor processes.

Direct Digital Control (DDC). In early systems, a single mainframe computer accomplished data acquisition, control, reporting to the operator, and higher-level computation. In the first systems, the computer directly controlled the process — without intervening controllers. This architecture was called direct digital control. See Fig. 2. Only one computer was used in the first systems because of the high cost per processor and because of the general absence of computer-to-computer communications. However, in the DDC system shown, an auxiliary (redundant) computer was proposed.

Early DDC system applications had a number of drawbacks. For example, if only one processor were used, a single failure could affect a large number of controlled variables and possibly disable an entire process. Although redundant processors were introduced to provide back-up for hardware failure, additional processors for functional distribution did not appear until much later.

Supervisory Control. This control concept, shown schematically in Fig. 3, developed over a period of years in an effort to use the many benefits available from the computer, but without the many drawbacks of DDC as previously mentioned. This concept had several advantages, in particular, it preserved the traditional panelboard control room while adding the capability of a digital computer with associated CRT displays. This minimized the disruption to operations that could accompany a transition to DDC. It also offered a buffer between the computer and the process — so that the operator had the option of selectively disabling the computer for troublesome loops. Although the impact of a computer failure was substantially reduced, it too used few processors. Thus, considerable functionality could still be disabled by a single failure.

Distributed Systems. This concept was introduced during the mid-1970s and combines three technologies, most of which either appeared for the first time or were much improved during the interim that dated back to DDC. See Fig. 4. These technologies are: (1) microprocessors, (2) data communications, and (3) CRT displays. Multiple microprocessors were used in one system as dedicated control loop processors. CRT operating stations and a variety of other control and communication functions. Although these systems could not always accomplish all the functions of the previous computer-based architectures, they achieved considerable fault tolerance by minimizing the effect of a single failure.

Hybrid Distributed Control Systems. Because distributed control systems are limited in computer functionality and in logic or sequential control, they often are combined with supervisory host computers and with programmable controllers in "hybrid" architectures as shown in Fig. 5. These systems use data communications channels between the host computer and both the programmable controllers and the distributed control system. Data communication between the programmable controllers and the DCS is also used although it is not always required. Although these systems offer the strengths of each subsystem, it is difficult to establish communication between the subsystems and often confusing to provide software inasmuch as each subsystem uses different programming techniques and organizes data in separate databases.

Single-Loop Controllers Replacing the DCS. In another version of the hybrid approach, the DCS is replaced by single-loop digital controllers. These offer some advantages in the precision of digital control, but still use a conventional panelboard as the primary operator interface rather than CRTs. This approach has limitations similar to the DCS hybrid approach except that the databases are inherently simpler because of the elimination of the CRT-based primary operator console.

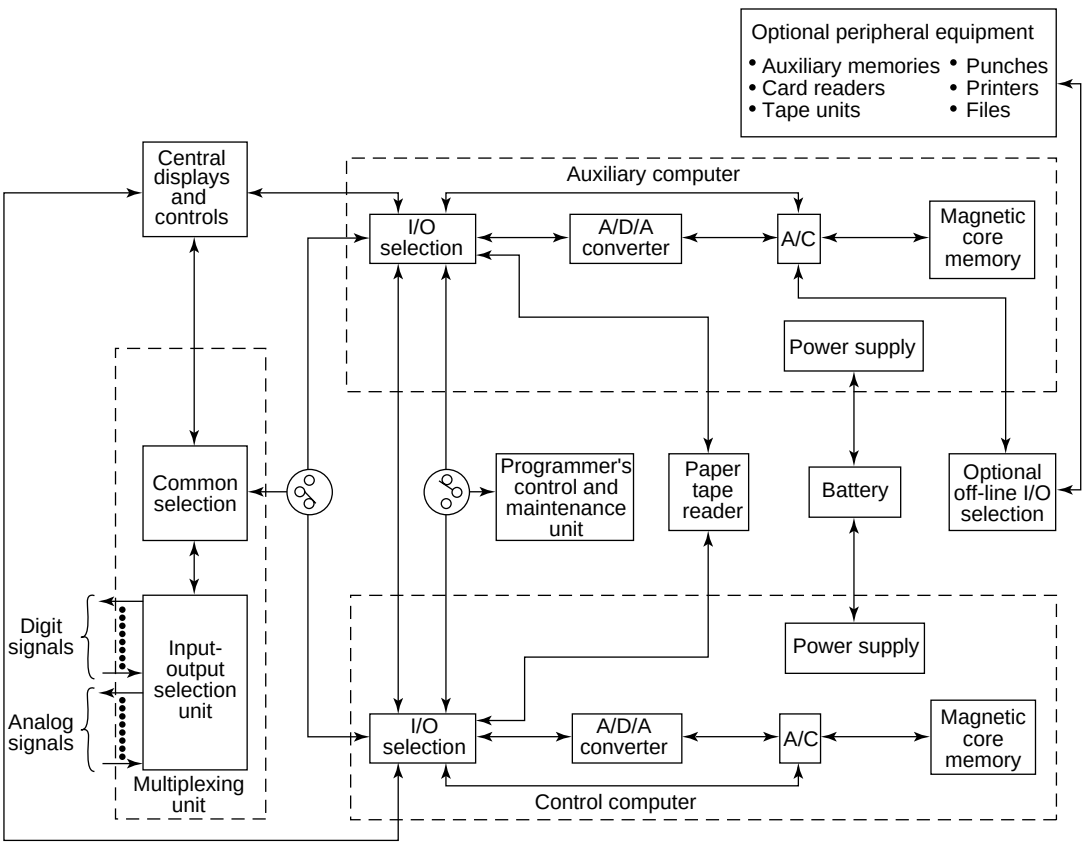

Fig. 2. Direct digital control system with auxiliary computers developed by Hughes Aircraft Company in 1965.

can be easily accessed. This display shows controller faceplate bargraphs of 8 to 16 loops and allows controller parameters, such as alarm limits, setpoints, controller mode, and controller output to be changed. *A detail display* of a single controller is often provided to allow additional parameters (e.g., controller tuning) to be changed. *Trend displays* are also available to plot process variables versus time to facilitate controller tuning and analysis of control upsets. *Process graphics* or *flowsheet displays* can be constructed to pictorially show process vessels, piping, and current operating conditions. Provisions are made to allow controller adjustments without leaving the flowsheet display. *Alarm annunciation displays* provide

a graphic representation of conventional alarm annunciator panels. These provide information on all alarms in the area on dedicated displays.

Keyboard designs vary widely among systems. Many are supplemented with methods of coordinating the operator's hand and eyes with touchscreens or joysticks, for example. Some suppliers offer touchscreen keyboards for highly flexible keyboard designs. The design of the keyboard must allow the operator quick access to any location for which there is operator responsibility. After an alarm is displayed at the operator station, a series of interactions or keystrokes allow access to the loop in alarm. By adjusting the setpoint, manually changing the valve position or other actions, the operator returns the process to normal operation. When this happens, the alarm will clear itself. Even if the process returns to normal without operator intervention, the alarm condition will remain in the system until it is acknowledged by the operator.

Two major considerations in selecting consoles are (1) prestructuring, and (2) backup. Console software as it is produced by the manufacturer should provide a complete set of prestructured displays and keyboard functions for loop controller display and operator actions, as well as for alarm display and acknowledgment. Absence of these features can add significantly to the implementation effort of the system user. In the event of a console failure, one console should be able to back up another. This seemingly simple requirement is not trivial in many systems. Not only must access be provided to all control points for both consoles, but alarm/acknowledge must be fully operational (without dual acknowledgment) for both the normal and failed console conditions.

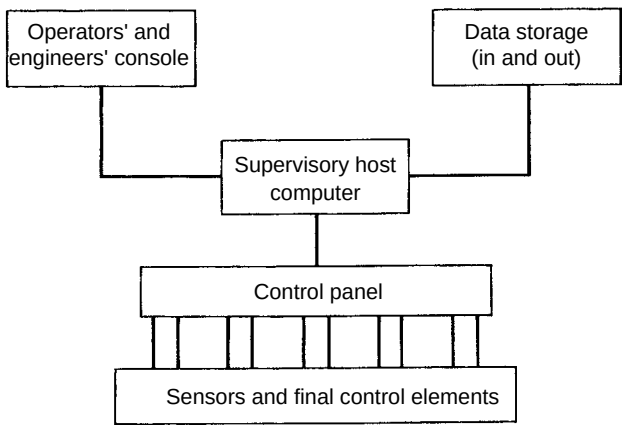

Fig. 3. Schematic diagram of a supervisory computer.

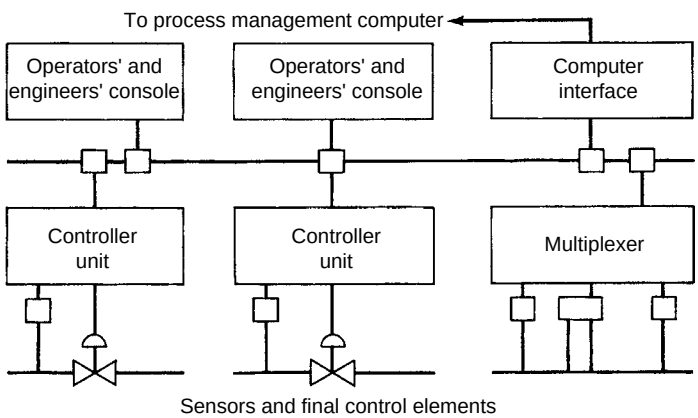

Fig. 4. Schematic diagram of an early distributed control system (DCS).

Operator consoles can be microcomputer- or minicomputer-based and usually can handle between 500 and 10,000 loops. The number of operator stations varies from one to four per computer processor. A disk is usually provided for additional display capability and when the console is used as a configuration station. In many cases, the console will remain-fully functional (minus some displays) in the event of disk failure.

Higher-Level Process Control

Process management functions traditionally have been handled by higher-level supervisory host computers. As "second generation" systems add to their capability, many process management functions also may be handled in the distributed control system (DCS). These functions, some of which are overlapping, are described as follows.

Historian. Data historian and event-recording functions traditionally have been in the domain of the host or supervisory computer. Large amounts of data require the storage capacity of large computer disks and tape drives. Retrieving the data in a short time requires the speed of a larger disk and significant computer power. Distributed control systems traditionally have been limited to floppy disks and low-end microprocessors. This has resulted in considerable shortage of storage capacity and often a slow speed of retrieval. Placing this function in the host has meant severe loading increases on the DCS highway and computer interface for large systems. Database and software of the host system must also be maintained separately, which contributes to the overall database maintenance effort.

Language-based Application Processor. Programming language capability of the type required for process modeling, complex calculations and optimization has also been primarily the domain of the supervisory host computer. Support for these functions can require considerable memory and processor power. Furthermore, process models and optimizing packages often exist in FORTRAN language. Distributed control systems traditionally have either lacked higher-level languages, or have been limited to proprietary BASIC-like languages, or (slow) interpretive BASIC. In many cases, language-based applications must be squeezed into already heavily loaded operator station processors.

Gateways. The control system must often exchange data with other plant subsystems, such as programmable controllers, weigh systems, gaging systems, and "smart" process analyzers. Although some standard gateways have been provided, any unusual communications link could not be accomplished by the DCS. In some cases, the DCS will have the electrical interface and the language required to complete the interface, but will lack the internal data communication power (throughput) to effectively pass this information through the system for use as process data in a control scheme, or as historical data. Host computers traditionally have provided much better flexibility for interfacing with other devices. However, sharing large amounts of this information with the DCS can become a loading problem, both for the computer and the DCS. If the data are regulatory-control related, the reliability of the host also can become an issue and the redundancy and functional isolation of a DCS may be an advantage.

Report Writers. Reports generated on demand or on a regular schedule are a key part of process supervisory functions. While most general purpose computers have comprehensive "forms" or other report-generating utilities, many distributed control systems have little capability. Packages should offer screen-oriented text editors with live data fields which can be updated when the report is generated.

Engineers' Workstation. A separate CRT workstation can be provided to analyze process data. Easy access to on-line and historical data is essential. The CRT should facilitate plotting data versus time and plotting one variable against another to establish interaction. A library of statistical functions and higher-level programming language capability should also be provided. The independence and security of the workstation must be assured so that its loading will have no effect on the operating process. The foregoing functions have required a supervisory computer in the past. In the future, personal computers and other microprocessor modules can be provided for this function as integrated components of a DCS.

Sequence-of-Events Processor. Although not a process management function, this function has been the province of the general-purpose computer for some time. Considerable speed and processing power is required to resolve the order in which process events occur (often to one millisecond).

Recipe Batch Unit. For batch control, records of product formulations and sequences of operation for their manufacture should be maintained and available as files in the control system. In the past, this required a host processor inasmuch as the products manufactured can number in the hundreds, to be further complicated with numerous grades of product, and other manufacturing variations for each product. File structures of the host

computer operating systems are well suited to product master recipe file handling. However, since these recipes must be directly transferable to the direct control processors for manufacturing, this function traditionally had computer interface and database limitations.

State-of-the-Art Distributed Control Systems

Distributed control systems can be considered in two classes: (1) those systems which reflect a predominant panelboard background; and (2) those systems which have a computer or "systems" background. The former class tends to be very structured in nature, with little computer sophistication required by the user, and with many protective features to help the user avoid inadvertent mistakes. The latter class tends to be more difficult to use, with fewer amenities to protect the user and, therefore, requires a higher degree of computer literacy. These systems are sometimes called "hard" and "soft" systems, respectively. See hybrid DCS briefly described in Table 2 and shown in Fig. 5. See also Table 3.

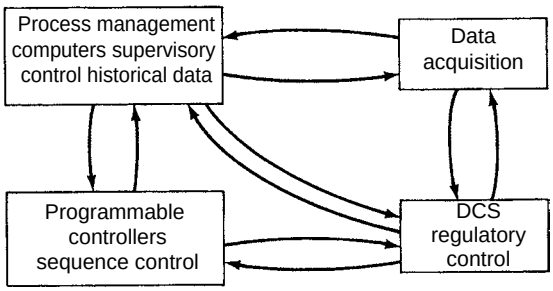

Fig. 5. Hybrid control system.

TABLE 3. KEY LIMITATIONS OF STATE-OF-THE-ART DISTRIBUTED CONTROL SYSTEMS

Sequencing — Programmable controllers are required to provide sequence control. Distributed control systems (DCS) in the past have provided only limited sequencing capability, most of which has been language-based and much slower (usually one second) to execute.
Calculation — Many DCSs have very little number processing capability. Math functions are often limited to a few very basic algorithms.
Communications — Linking the DCS with host computers and other intelligent devices, such as programmable controllers and smart analyzers, has been difficult.
Capacity — DCSs have been severely limited in the number of points that can be handled on a single highway and by a single console.
Programming — Although fill-in-the-blanks configuration is desirable for most direct control functions, higher-level language is desirable for many complex functions, such as process modeling. For these needs, FORTRAN or other standard languages are desirable. Proprietary languages are undesirable since they require special training for programmers and do not allow transport of software between systems.
Lack of Integration — Past attempts to add sequencing and other functions have led to separate databases configured from separate workstations. As functions are added, they should appear to the user as having a unified database structure. In general, the duplication of databases within the system should be avoided and, where required, should be made transparent to the user.
User Orientation — The limited need for both user software and unstructured computer-like environments should be continued. Database setup of control systems should remain highly structured. Direct control functions should require very little computer literacy. Entering and modifying routine control should be fully protected against corruption of unrelated system functions and unidentified errors in compilation or downloading. A comprehensive, error-free set of functions for both continuous and sequential operation should be maintained with easy-to-use and well-defined procedures for application and modification.

In general, developments in DCS systems will allow a transition from the hybrid systems of the past to more fully integrated systems. See Figs 6 and 7. In the hybrid approach, the DCS was one of several subsystems in the control hierarchy at the direct control level, including programmable controllers and the supervisory computer, which had

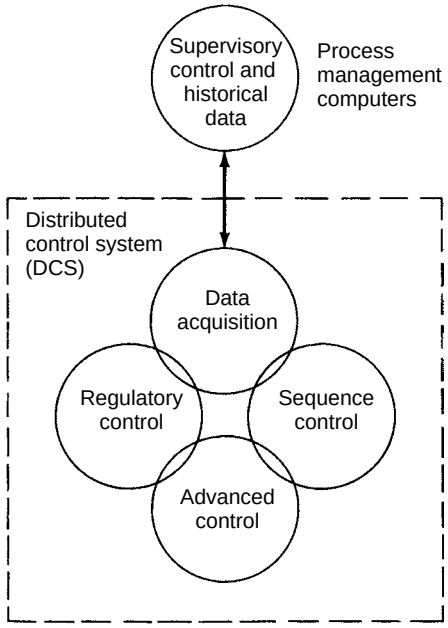

Fig. 6. Integrated distributed control system (DCS).

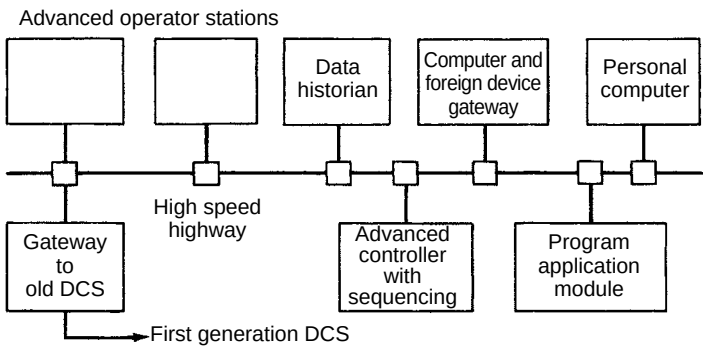

Fig. 7. Second-generation distributed control system (DCS).

considerable regulatory control functionality. DCS systems are now progressing toward inclusion of most of the direct control functions and numerous process management functions.

Through redundant processors and limited functionality per processor (functional separation), digital technology has been well established as having reliability as good as or better than the traditional analog control which was essentially the only control approach available for many years. For critical functions of safety interlocking, where personnel of equipment are endangered, additional sophistication in design will be required. Two examples are: (1) two-out-of-three voting, and (2) fail-safe electronics.

Two-out-of-three voting is a scheme wherein signals are input to the system on three separate paths to each of three separate processors. Through an elaborate algorithm, the processors decide the validity of the data. Each processor then issues a corresponding output, which is processed by the output logic to decide what the valid output is. By requiring that two signals must match in both of these cases, the probability of an error in processing due to a single failure is eliminated.

The fail-safe electronics approach addresses the unpredictability of electronic output circuits. Normally, it has been impossible to predict whether an electronic circuit will fail when "on" or "off" (high or low, etc.). With this type of circuit, the failure state can be accurately determined. The technique currently is becoming available on a limited basis. It is interesting to note that control engineers, particularly those in the process industries, over the years became accustomed to fail-safe devices as, for example, a control valve purposely configured to fail open or fail closed.

Considerable improvement is also possible in the area of system *self-diagnosis*. When a system fails, a full English language description of the failure and how to handle it should be almost instantly available to the operator.

Designing for Plantwide Control

For plantwide control, numerous functions not previously described are required. There are additional layers to the hierarchy required and this increases the overall communication and database access task. Factory floor automation is moving along a path toward standardized communication (example: MAP, developed by General Motors) and toward *open-system* architectures. In this type of architecture, all subsystems on a network can uniformly access data from other subsystems. No similar direction has been established for process control systems, such as distributed control systems. A number of manufacturers have agreed to provide General Motors MAP gateways, but it is likely that many suppliers will continue for awhile to use proprietary communication schemes within their own systems. To the system user, all points of data in the system should be accessible in a uniform manner without concern for where it is located within the system. This is sometimes referred to as a *global database* concept. To achieve plantwide control, fully integrated systems with truly global database access must be achieved. See Table 4.

TABLE 4. KEY LIMITATIONS OF STATE-OF-THE-ART HOST COMPUTER SYSTEMS

Programming — In the past, host computers have required a high degree of programming and operating system expertise by the user. Although the addition of high-level, user-oriented packages for reports and database maintenance has reduced this need in some areas, these systems require considerable improvement to achieve "user friendliness."
Lack of Integration — Like other subsystems in the control hierarchy, most computers suffer the effects of poor integration with the rest of the system. Not only must a separate database be defined and maintained for the host computer, but also independent operator stations, often with unique operating procedures, must be used to access the host data.
Speed — Because of the limited number of processors at the host computer level, many points and functions are usually processed together. Because of this, the speed of response can be a serious problem. Data acquisition operator and engineer workstation, and database access can all experience significant delays in a heavily loaded system.
Reliability/Security — These have been key limitations of host computers. Because they are not functionally distributed, the operating environment can be very complex, increasing the probability of user error. In addition, there usually are large amounts of process data in the host computer. These systems traditionally have been vulnerable to downtime because of user errors and scheduled or unscheduled maintenance.
Communications — Although host computers have good flexibility to accommodate data links to other computers and intelligent devices, they have been limited in capacity for large amounts of data. Slow-speed data links in particular have contributed to processor loading and have been low in efficiency. Special software interfaces have been required on many devices because few comprehensive standards have existed for communication between systems.

Potential of Artificial Intelligence

Although control system features with some artificial intelligence (AI) capability are relatively new, it is expected that many improvements to system performance will be in these areas, particularly in the "expert system" area. In the relatively near future, all distributed control systems should offer self-tuning on their regulatory algorithms. Advanced alarming should also be offered. This capability will allow alarm grouping and sequence of occurrence to be used to let the system recommend corrective action to the operator that is based on programmed "intelligence" about the process. Although AI will require significantly more memory, speed, and processing power than is currently available in control systems, this type of feature could begin to capture human experience (from past incidents, for example) that can be used in running a process and that can be available to operators who may be less familiar with how to respond to process problems and emergencies. Before there is widespread use of AI techniques, much more development is required. See also **Artificial Intelligence**.

Personal Computers

Several personal computers currently available are enhancing control system capability, as in recipe handlers for batch control, configuration database generation and management, and configuration self-documentation. These new capabilities (sometimes called *second-generation*) will allow the distributed control system to take on a more central role in assuming a more complete set of direct control and process management functions. In doing this, it will become a larger portion of the control system hierarchy. In practice, the added capability of the first-level system will mean the migration of functions previously relegated to higher-level systems to first-level DCS. This will provide additional choices for system architecture.

CONTROL VALVE. See **Valve (Control)**.

CONVECTION. 1. In general, mass motions within a fluid resulting in transport and mixing of the properties of that fluid. Convection, along with conduction and radiation, is a principal means of energy transfer. Distinction is made between free convection (gravitational or buoyant convection), motion caused only by density differences within the fluid; and forced convection, motion induced by mechanical forces such as deflection by a large-scale surface irregularity, turbulent flow caused by friction at the boundary of a fluid, or motion caused by any applied pressure gradient. Free and forced convection are not necessarily exclusive processes. On a windy day with overcast sky, the heat exchange between ground and air is an example of forced convection. On a sunny day with a little wind where the ground temperature rises, both kinds of convection take place.

2. (Or gravitational or buoyant convection.) Motions that are predominantly vertical and driven by buoyancy forces arising from static instability, with locally significant deviations from hydrostatic equilibrium.

Atmospheric convection is nearly always turbulent. Convection may be dry, that is, with relative humidities less than 100%, especially in the boundary layer, but is commonly moist, with visible cumuliform clouds. Most convective clouds are driven by positive buoyancy, with virtual temperature greater than the environment, but clouds with precipitation, evaporation, and/or melting can produce negatively buoyant convection.

3. As specialized in atmospheric and ocean science, a class of relatively small-scale, thermally (can be driven by salt concentration in the ocean) direct circulations that result from the action of gravity upon an unstable vertical distribution of mass. (In the case of slantwise convection, though, the motions are larger scale, and are driven by a combination of gravitational and centrifugal forces acting at an angle to the vertical.)

Almost all atmospheric and oceanic convection is fully turbulent and is generally composed of a collection of convection cells, usually having widths comparable to the depth of the convecting layer. In the

atmosphere, convection is the dominant vertical transport process in convective boundary layers, which are common over tropical oceans and, during sunny days, over continents. In the ocean, convection is prominent in regions of high heat loss to the atmosphere and is the main mechanism of deep water formation. Moist convection in the atmosphere is characterized by deep, saturated updrafts and downdrafts, and unsaturated downdrafts driven largely by the evaporation and melting of precipitation. This form of convection is made visible by cumulus clouds and, in the case of precipitating convection, by cumulonimbus clouds. Moist convection and radiation are the dominant modes of vertical heat transport in the Tropics. See also **Convection Cell**.

4. In atmospheric electricity, a process of vertical charge transfer by transport of air containing a net space charge, or by motion of other media (e.g., rain) carrying net charge.

Eddy diffusion of air containing a net charge gradient may also yield a convection current.

Slantwise Convection. A form of convection driven by a combination of gravitational and centrifugal forces. Slantwise convection can occur in baroclinic flows in which the slantwise-upward displacement of air parcels, elongated in the direction of the thermal wind, results in a vector combination of buoyancy and Coriolis (or centrifugal) and pressure-gradient accelerations that drive the parcel in the same direction as the displacement.

CONVECTION CELL. 1. An organized unit of convection within a convecting layer. It is isolated by a stream surface, with ascending motion in the center and descending motion near the periphery, or vice versa. In laboratory convection, such cells (sometimes referred to as Bénard cells) are usually roughly as deep as they are wide, may take the form of squares, triangles, or hexagons, and may be laminar or turbulent and steady or oscillatory. In atmospheric boundary layer convection, this term refers to an organization of turbulent convection on horizontal scales at least as large as the depth of the convective boundary layer. In the case of cloud-topped boundary layers, convection cells may take the form of open cells, with broad, cloud-free areas of gentle descent surrounded by narrow updrafts within cumulus clouds, or may take the form of closed cells in stratocumulus clouds, characterized by narrow downdrafts at the periphery.

2. In the case of precipitating moist convection, refers to a distinct unit of convection, often having its own closed contours of radar reflectivity and a lifetime of roughly 20–30 minutes. Such a cell generally begins as a cumulus updraft, then develops a precipitation-driven downdraft, and finally decays as a general, cloudy area containing weak downdrafts.

CONVECTION CURRENT. 1. (Or convective current.) Any current of air involved in convection. In meteorology, this is usually applied to the upward moving portion of a convection circulation, such as a thermal or the updraft in cumulus clouds.

2. Any net transport of electric charge effected through mass motions of some charged medium; any electric current induced by other than electrical forces. In atmospheric electricity, the convection current is part of the air-earth current of charge transfer vertically between the earth's surface and the upper atmosphere. The term includes not only eddy diffusion currents existing in regions of net space charge but also currents due to fall of charged precipitation particles (precipitation current). See also **Convection**; **Precipitation Current**.

CONVECTIVE ADJUSTMENT. A method of representing unresolved convection in atmospheric models by imposing large-scale vertical profiles when convection occurs. See also **Convection**.

As originally developed, convective adjustment was applied when modeled lapse rates became adiabatically unstable. New temperatures were calculated for unstable layers by conserving static energy and imposing an adiabatic lapse rate. If, in addition, humidities exceeded saturation, they were adjusted to saturation, with excess water removed as precipitation. A related adjustment, (stable saturated adjustment), for stable layers with water vapor exceeding saturation, returned them to saturation, also conserving energy. More recently, convective adjustments have been developed that adjust to empirically based lapse rates, rather than adiabatic lapse rates, while still maintaining energy conservation. Convective adjustment is generally applied to temperature and humidity but, in principle, can also be applied to other fields affected by convection.

AMS

CONVENTION DU MÈTRE. The Convention du Mètre was signed in Paris on 20 May 1875 by 17 states during the final session of the Diplomatic Conference of the Mètre, http://www.bipm.fr/en/convention/. This Convention was amended in 1921.

The highest authority is the Conférence Générale des Poids et Mesures (CGPM). It consists of delegates from all member states of the Convention du Mètre (1992: about 50) and at present meets every four years. It is responsible for the following:

- discussing and instigating the arrangements required to ensure the propagation and improvement of the International System of Units (SI), which is the modern form of the metric system;
- confirming the results of new fundamental metrological determinations and the various scientific resolutions of international scope; and
- adopting the important decisions concerning the organization and development of the BIPM.

The Comité International des Poids et Mesures (CIPM) operates under the authority of the CGPM and consists of 18 members, each coming from a different state; it meets at present every year.

In view of the extension of the work entrusted to the BIPM (Bureau International des Poids et Mesures), the CIPM has set up since 1927, under the name of Comités Consultatifs (CC), bodies designed to provide it with information on matters it refers to them for study and advice. These CCs are responsible for coordinating the international work carried out in their respective fields and proposing recommendations for units. At present, there are nine of them in existence:

1. the Comité Consultatif d'Electricité (CCE), set up in 1927;
2. the Comité Consultatif de Photométrie et Radiométrie (CCPR), basically set up in 1933;
3. the Comité Consultatif de Thermométrie (CCT), basically set up in 1937;
4. the Comité Consultatif pour la Définition du Mètre (CCDM), set up in 1952;
5. the Comité Consultatif pour la Définition de la Seconde (CCDS), set up in 1956;
6. the Comité Consultatif pour les Etalons de Mesure des Rayonnements Ionisants (CCEMRI), set up in 1958;
7. the Comité Consultatif des Unités (CCU), set up in 1964;
8. the Comité Consultatif pour la Masse et les Grandeurs Apparentées (CCM), set up in 1980; and
9. the Comité Consultatif pour la Quantité de Matière (CCQM), set up in 1993.

The BIPM was set up by the Convention du Mètre in 1875. It has its headquarters near Paris, on the grounds of the Pavillon de Breteuil (Parc de Saint-Cloud). The BIPM operates under the exclusive supervision of the CIPM. Its task is to ensure worldwide harmonization of physical measurement; it is responsible for

- conserving and disseminating the unit of mass;
- establishing and disseminating the International Atomic Time and, in collaboration with the appropriate astronomical organizations, Universal Coordinated Time;
- providing a center for the international comparison of the realizations of other base or derived units; this requires that in some areas the BIPM should maintain its own realizations of certain base or derived units;
- determining, where appropriate, physical constants closely related to the definition, realization, or dissemination of base or derived units; and
- ensuring that the results of international comparisons are properly documented and published, if not elsewhere, directly by the BIPM.

CONVERGENCE. A sequence $\{S_n\}$ converges if it has a limit. The same statement holds for an infinite series S_n if that symbol is regarded as the sum to n terms of the series $S_1 + (S_2 - S_1) + (S_3 - S_2) + \cdots + (S_n - S_{n-1})$.

There are several ways in which a sequence or series can be examined for convergence. See also **Cauchy Convergence Test**.

When a series is shown to be convergent, it can be further classified as absolutely convergent, if the sum of its terms without regard to sign

approaches a limit; nonabsolutely convergent (or divergent), if it is not absolutely convergent. If a series continues to give the same sum no matter how its terms are added, it is absolutely convergent; otherwise, conditionally convergent.

CONVERSION. 1. In its most general usage, this term denotes a change, often with the force of a directed or induced change. One specific use is a change in numerical value of a quantity resulting from the use of a different unit in the same or a different system of measurement. 2 An intramolecular rearrangement of organic substances in which the relative positions of the radicals are modified. The Beckmann rearrangement is a case in point. Radicals may be transferred from carbon, oxygen, or nitrogen to carbon; from carbon or oxygen to nitrogen; from side chains to nucleus, etc. 3. The process of changing information from one form of representation to another; such as, from the language of one type of machine to that of another or from magnetic tape to the printed page. 4. The process of changing from one data processing method to another, or from one type of equipment to another; e.g., conversion from punch card equipment to magnetic tape equipment.

CONVERSION COATINGS. The industrial application of organic finishes to metals almost always requires the use of an intermediate conversion coating, particularly when the performance demands are high. Conversion coatings are formed chemically by causing the surface of the metal to be "converted" into a tightly adherent amorphous or crystalline coating, part or all of which consists of an oxidized form of the substrate metal. Conversion coatings can provide high corrosion resistance as well as strong affinity for organic coatings. They are also useful as lubricants for the drawing and forming of metals and sometimes are used for decorative purposes. The most important and widespread use of conversion coatings is on steel, zinc or galvanized steel, and aluminum alloys. The most widely used classes of conversion coatings for use on these metals are the phosphates and chromates. Depending on size, shape, volume of production, and other factors, the coating may be applied by spray, immersion, roll coat, or brush. A typical metal pretreatment sequence is: (1) cleaning; (2) rinsing; (3) conversion coating; (4) rinsing; and (5) final rinsing.

Phosphating of Steel

When a ferrous alloy is immersed in phosphoric acid, it initially forms a soluble phosphate. As the pH rises at the metal/solution interface, the phosphate becomes insoluble and crystallizes epitaxially on the substrate metal. The phosphate coating thus produced consists of a nonconductive layer of crystals that insulates the metal from any subsequently applied film and provides a topography with enhanced "tooth" for increased adhesion. The crystals insulate microanode and microcathode centers caused by stress or imperfections in the metal surface. This greatly reduces the severity of electrochemical corrosion.

Practically all phosphating processes involve patented proprietary solutions which produce superior coatings in shorter times and at lower temperatures than are obtainable with phosphoric acid alone. Treating times have been reduced from the earlier 1–2-hour to 1–5-minute periods, while temperatures have been reduced from 98 to 20–30 °C.

Increasing energy costs have led to more widespread use of low-temperature phosphatizing baths. These comprise a lower free acid content which results in higher saturation of the primary zinc phosphate and thus provides a greater tendency to deposit at temperatures at or close to ambient temperature. In many cases, depending on the type of soil, it is difficult to reduce the cleaner temperature and, as a result, the cleaned parts tend to heat the phosphatizing stage to approximately 50 °C even when no external heat is used.

Iron Phosphate Coatings

These coatings, weighing about 40–60 milligrams per square foot (430–646 milligrams per square meter), provide good paint adhesion, but inferior heat and corrosion resistance. They are used when coating performance is not very demanding. Iron phosphate coatings appear as a very thin blue or brown film to the naked eye.

Crystalline Zinc Phosphate Coatings

These coatings, weighing about 200 milligrams per square foot (2152 milligrams per square meter) when applied by spray, or as much as 3000 milligrams per square foot (32,280 milligrams per square meter) when applied by immersion, are of a medium-gray color and are used when higher quality is mandatory. For even greater corrosion resistance and paint adhesion, *microcrystalline zinc phosphate* coatings are used. They are dark in color and give coating weights of about 150–200 milligrams per square foot (1614–2152 milligrams per square meter) when sprayed and up to 1000 milligrams per square foot (10,760 milligrams per square meter) when applied by immersion. They are used as a paint base for products which are expected to last for years under varying environmental conditions.

Phosphating Chemistry

Iron and iron oxide react with phosphoric acid to form soluble primary iron phosphate, $Fe(H_2PO_4)_2$, liberating H_2 and H_2O, respectively. Due to the consumption of acid at the metal interface, there is a local rise in pH, which causes insoluble secondary iron phosphate, $FeHPO_4$, to coat the metal. The iron in the coating is supplied by the substrate.

In zinc phosphating, a small amount of iron phosphate is formed initially, but the bath contains primary zinc phosphate, $Zn(H_2PO_4)_2$, which crystallizes on the metal surface as secondary and tertiary zinc phosphates, $ZnHPO_4$ and $Zn_3(PO_4)_2$, respectively, when the pH rises at the metal/solution interface. The most frequently used baths contain accelerators, preferably nitrates and nitrites, which oxidize the hydrogen formed by the pickling reactions. The fundamental zinc phosphate reactions occur in three steps, all in the same bath:

$$Fe^0 + 2H^+ \rightarrow Fe^{++} + \underset{\text{(Pickling)}}{H_2}$$

$$3Fe^0 + 2NO_3^- + 8H^+ \rightarrow 3Fe^{++} + 2NO + \underset{\text{(Coating)}}{4H_2O}$$

$$3Fe^{++} + 2H_2PO_4^- \rightarrow 4H^+ + Fe_3(PO_4)_2$$

$$3Zn^{++} + 2H_2PO_4^- \rightarrow 4H^+ + \underset{\text{(IronRemoval)}}{Zn_3(PO_4)_2}$$

$$4Fe(H_2PO_4)_2 + O_2 \rightarrow 4FePO_4 + \underset{\text{(sludge)}}{4H_3PO_4} + 2H_2O$$

$$Fe(H_2PO_4)_2 + NaNO_2 \rightarrow FePO_4 + NO + \underset{\text{(sludge)}}{H_2O} + NaH_2PO_4$$

In the coating reaction, each 3 moles of iron or zinc liberates 4 moles of hydrogen ion. However, in the pickling reaction, 8 moles of hydrogen ion are consumed. Thus, the pH at the metal interface rises, and insoluble tertiary ferrous phosphate and zinc phosphate crystallize on the iron surface. The coating closest to the metal interface is largely iron phosphate, while that farther away is rich in zinc phosphate.

Iron buildup in the bath is objectionable; in the iron-removal equations above, it is seen that dissolved Fe^{++} can be removed by oxidation, slowly in air or more rapidly by peroxides or nitrite, as shown in the final equation. The iron removed becomes ferric phosphate, while iron in the coating is ferrous phosphate.

Accelerators speed phosphating reactions by reacting with hydrogen liberated at the metal. Were hydrogen not removed, it would form gas bubbles which would interfere with metal/solution contact. Strong oxidizer accelerators also serve to precipitate dissolved iron and, to a degree, act as metal cleaners by oxidizing residual organic soils. In spray application, mild accelerators are usually adequate for maintaining dissolved iron at safe levels because atomization of the solution permits it to absorb from air the oxygen needed for precipitation of iron.

Zinc phosphate coatings consist of varying ratios of hopeite, $Zn_3(PO_4)_2 \cdot 2H_2O$, and phosphophyllite, $Zn_2Fe(PO_4)_2 \cdot 4H_2O$, with hopeite usually predominant. Hopeite and phosphophyllite grow epitaxially on alpha-iron crystallites. Only a slight adaptation deformation is necessary for the lattice planes of both foreign phases compared with the alpha-iron lattice of the substrate. Good adhesive strength can be expected from such a bond.

The smaller the crystals, the better the adhesion: crystal-to-metal, crystal-to-crystal, and crystal-to-final finish. Also, the smaller the crystals, the tighter the packing, the denser the coating, the less total porosity area for corrosive reactions to take place.

Crystal size depends upon such factors as growth rate, agitation, and the effects of nucleating agents and foreign atoms in the crystal lattice. Spray application provides agitation which reduces crystal size. Accelerators increase the number of nucleation sites on the substrate and result in smaller

crystals. The most refined technique for producing very small crystals is the introduction of foreign elements of different atomic radii into the crystal lattice. A calcium additive in a zinc phosphating solution produces scholzite, $CaZn_2(PO_4)_2 \cdot 2H_2O$, in which the crystals may average one-twentieth the size of the finest crystals produced by other methods. It is believed that the foreign elements cause uneven growth along one crystal face, creating stresses that either stunt growth at an early stage, or rupture the crystal.

The relatively recent surge into the use of cathodic electrodeposition, especially in the automotive industry, has necessitated change in the metal pretreatment. The generation of hydroxyl ions at the cathode where the organic coating is deposited tends to dissolve zinc from the conventional zinc phosphate conversion coating with consequent deleterious coating performance. By increasing the concentration of phosphoric acid in the zinc phosphatizing stage, the ratio of iron to zinc in the conversion coating is increased. Such conversion coatings show superior performance under cathodically electrodeposited coatings.

The following sequence is typical of a production spray phosphate system: (1) cleaning for 60 seconds at 71–77°C; (2) rinsing for 15 to 30 seconds (hot or cold); (3) phosphating for 60 seconds at 54–60°C; (4) rinsing for 15–30 seconds (cold); and (5) chromate-rinsing for 30–45 seconds at 27–60°C. The final stage, an acid chromate rinse, is extremely important to the overall adhesion and corrosion resistance of the finish. One of its functions is to seal the pores in the phosphate coating. The effect can be demonstrated by placing a drop of chromic acid in the center of a phosphatized panel and subjecting it to corrosive exposure. Corrosion in the chromated area will be strongly inhibited.

Phosphating of Zinc

The chemistry in the phosphating of zinc alloys is similar, with the exception that iron does not play an important role in the coating or in the bath. The only cation involved is Zn. Zinc phosphate coatings are used widely in the treatment of galvanized steel for refrigerators, air conditioners, kitchen cabinets, and house and building siding.

Aluminum Pretreatment

Although A1 protects itself against corrosion by forming a natural oxide, the protection is not complete. In the presence of moisture and electrolytes, A1 alloys, particularly the high-copper alloys, corrode much more rapidly than pure A1.

Chemically produced oxides can be formed by treatment in 2–3% sodium carbonate containing 0.1% sodium dichromate for 10–20 minutes at 66°C, followed by "sealing" in 5% sodium dichromate at 82–88°C for 10 minutes. Such coatings are softer, more porous, and not as effective as those produced by chromic acid anodizing.

Electrically produced anodic coatings from chromic, sulfuric, or oxalic acid electrolytes are more dense and less porous. Their corrosion resistance is improved by hot-water sealing, which is even more effective with the inclusion of dichromate.

Generally, the higher the alloy content of the base aluminum, the heavier the oxide present and the more difficult it is to remove prior to effective chemical pretreatment. A properly formulated deoxidizer will remove the oxide only to the desired degree, with minimum attack on the base metal. The baths usually consist of fairly high concentrations (5–10%) of either nitric or sulfuric acid, along with chromates and either free or complex fluorides. A deoxidizer will also remove the smut that forms on etching in strong alkali. Smut consists of the alkali-insoluble alloying elements and their oxides.

Amorphous Phosphate Coatings for Aluminium

These coatings were introduced in 1945. Their simplicity of operation, speed, and economy have resulted in wide commercial acceptance. They provide a continuous uniform green coating with excellent paint-bonding properties and underfilm corrosion protection. The coatings consist of varying ratios of chromic phosphate and hydrated aluminum oxide. The bath contains hydrofluoric acid, which removes the natural oxide to permit contact of the coating- forming chemicals with the metal. The complexity of the reactions involved makes it difficult to present a simplified chemistry, but the results of many tests and analyses give the following coating composition: $x\mathrm{CrPO_4} \cdot y\mathrm{Al2O_3} \cdot z\mathrm{H_2O}$. The phosphate coatings vary from 10 to 300 milligrams per square foot (108 to 3228 milligrams per square meter), depending on the end use. The lower coating weights are used for paint bonding; the higher range is used for decorative purposes.

Gold-colored conversion coatings are formed in baths containing hydrofluoric acid to remove the natural oxide, and chromic acid. The coating composition is chromic chromate plus varying amounts of hydrated aluminum oxide. Some baths also contain ferricyanide iron, which greatly accelerates the coating action and forms some chromic ferricyanide in the coating. This constitutes one of the most widely used conversion coatings on aluminum because of its high speed, excellent corrosion resistance, and high affinity for organic finishes. The hexavalent chromium content permits these coatings to withstand somewhat more severe corrosive environments than do the amorphous phosphate coatings. The baths have a pH of about 1.2–1.9 and can be applied by dip, brush, spray, or reverse roll coater.

Proprietary chromate rinses are frequently used over conversion coatings on aluminum for increased corrosion resistance. See also **Autodeposition**.

WILBUR S. HALL, Amchem Products, Inc., Ambler, Pennsylvania

CONVERSION GAIN RATIO. In communications, the ratio of the available signal power at the output to the available signal power at the input of a frequency converter or mixer.

CONVERSION RATIO. 1. The ratio of the number of internal conversion electrons to the number of gamma rays emitted in a given time interval by a single nuclidic species during the de-excitation of one of its excited energy states. Sometimes known as the *internal-conversion coefficient*. 2. In a nuclear reactor, the number of fissionable atoms produced per fissionable atom destroyed. See also **Nuclear Power Technology**.

CONVOLUTION. If f and g are both functions of the complex variable z, the convolution or *faltung* of f and g, often indicated by the symbol $(f * g)$ is the integral

$$(f * g) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(t)g(z-t)\,dt$$

Let F be the Fourier transform of the integral, then $F(f * g) = F(g * f) = F(f)F(g)$. This theorem also applies directly to the Laplace transform and, with minor modifications, to the Mellin transform.

The German word *faltung* means "folding." It is used in this case for the following reason. Let a line of length z be folded back in the middle as shown in Fig. 1. The points opposite each other on its two parts then lie at distances of t and $(z - t)$ from the origin.

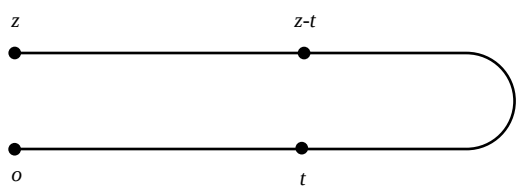

Fig. 1. Convolution.

If $F_1(x)$ and $F_2(x)$ are the distribution functions of two random variables, their convolution is defined as

$$F(x) = \int_{-\infty}^{\infty} F_2(x-t)dF_1(t) = \int_{-\infty}^{\infty} F_1(x-t)dF_2(t)$$

If the variables are independent, $F(x)$ is the distribution function of their sum, and the expression "sum of random variables" is to be understood as convolution in this sense.

Analogously, a number of variables have a convolution given by

$$F(x) = \int_{-\infty}^{\infty} dF_1(t_1) \cdots \int_{-\infty}^{\infty} F_n(x - t_1 - \cdots - t_{n-1})dF_{n-1}(t_{n-1})$$

CONVULSION. A violent, uncontrollable contraction or series of contractions of voluntary muscles. It may or may not be accompanied by loss of consciousness. See **Seizure (Neurological)**; and **Central and Peripheral Nervous Systems**.

COOLANT. Any liquid or gas having the property of absorbing heat from its environment and transferring it effectively away from its source. Coolants are used in all types of automobiles, as well as in chemical processing and nuclear engineering equipment. One of the most effective and cheapest coolants is water, which is almost universally used in automotive and ordinary reaction equipment. Air is also used. Where intense heating requires a more efficient medium, special coolants are used; liquid sodium in nuclear reactors, liquid hydrogen in high-thrust nuclear rocket engines; carbon dioxide, propylene glycol, and "Dowtherm" in chemical-processing reactors. Methoxy propanol has been introduced for diesel engines. Some coolants provide antifreeze protection.

See also **Antifreeze Agents**.

COOLING CURVE. A graph of the temperature of a substance plotted against time, such as is obtained for a molten alloy cooling through its solidification temperature or range of temperatures.

COOLING POWER. See **Meteorology**.

COOLING TEMPERATURE. See **Meteorology**.

COORDINATES (Generalized). (Also called Lagrangian Coordinates). Any set of coordinates specifying the state of the system under consideration. Usually employed in problems involving a finite number of degrees of freedom, the generalized coordinates are chosen so as to take advantage of the constraints of the system in reducing the total number of coordinates. See also **Lagrangian Coordinates**.

COORDINATE SYSTEM. A coordinate is one of a set of numbers used to locate a point relative to a system of axes or surfaces, the coordinate system. The simplest and most frequently used system is called rectangular Cartesian. Choose three mutually perpendicular straight lines, the coordinate axes, intersecting at a point O, the origin. Label the axes OX, OY, OZ and imagine that OX and OY are drawn on a piece of paper, the XY-plane, so that the positive direction of OX points toward the reader's right and the positive direction of OY points toward the top of the page. The positive direction of OZ is then taken upward from the page, toward the reader. This arrangement determines a right-handed coordinate system, the most common one. If a pair of axes is exchanged, the system is then left-handed. A unit distance of convenient size is selected and this distance is marked off on each axis, repeatedly and in both positive and negative directions. Now suppose three numbers are given, one each in multiples (or fractions) of the unit distance along each axis. The numbers then locate the position of a point in space, relative to the coordinate system and they are the coordinates of the point. A suitable notation is (x, y, z). If one coordinate is zero, the point is on one of the three possible planes of the system, a coordinate surface; if two coordinates vanish, the point lies at the intersection of two coordinate surfaces, which is a coordinate axis; if all three coordinates are zero, the point is at the coordinate origin.

When a given point lies on a coordinate surface, it is customary to use the XY-plane. The horizontal coordinate is then called the abscissa and measured along the X-axis while the vertical, or Y-coordinate, is called the *ordinate*.

These conceptions can be generalized extensively. When the surfaces are mutually perpendicular, the system is curvilinear or orthogonal; when the surfaces are orthogonal planes, the system is rectangular; if the surfaces do not intersect at right angles, the system is said to be affine or nonorthogonal. A Cartesian coordinate system could mean a rectangular system or a system of planes not at right angles to each other. The latter is called an oblique coordinate system. However, the term Cartesian generally means rectangular Cartesian.

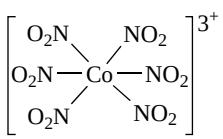
After Cartesian coordinates, the next most often used type is the polar coordinate in two or three dimensions, the latter being called spherical polar coordinates. The two-dimensional case is appropriate for the study of many plane curves and for the complex variable (see also **Argand Diagram**). Systems of three axes in a plane or four axes on the sides of a tetrahedron, called trilinear and quadriplanar coordinates, respectively, are sometimes applicable to special problems.

Many problems in chemistry and physics involve partial differential equations and these often require for their solution a suitable coordinate system so that the method of separation of variables can be used. While the geometry or symmetry of a given problem frequently suggests the correct coordinate system, considerable attention has been paid to a more general problem about coordinate systems. One attempts to derive all systems that will yield separation of variables under certain general conditions as permitted by a partial differential equation. The solution to this problem is known for the Schrödinger wave equation of quantum mechanics and the eleven possible systems in this case are: rectangular, conical, cylindrical, ellipsoidal, elliptic cylindrical, spheroidal (either oblate or prolate), parabolic, parabolic cylindrical, paraboloidal, spherical polar. Laplace's equation also separates in these eleven systems and in bipolar and toroidal coordinates.

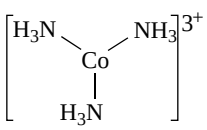
In addition to these coordinate systems which differ in the geometry upon which they are based, there are also the generalized coordinates of Lagrange, Lagrangian coordinates, natural coordinates, relative coordinates, inertial coordinates, and Eulerian coordinates. These systems are especially useful in mechanics, meteorology, and other physical problems.

COORDINATION COMPOUNDS. One of a number of types of complex compounds, usually derived by addition from simpler inorganic substances. Coordination compounds are essentially compounds to which atoms or groups have been added beyond the number possible on the basis of electrovalent linkages, or the usual covalent linkages, to which each of the two atoms linked donates one electron to form the duplet. The coordinate groups are linked to the atoms of the compound usually by coordinate valences, in which both the electrons in the bond are furnished by the linked atom of the coordinated group. The amines and complex cyanides are representative of coordination compounds.

In attempting to classify coordination compounds, Sidgwick noted that the number of molecules or atoms coordinated with a metallic atom (which he called *coordination number*) is 2, 3, 4, 5, 6, or 8, and that 2, 4, and 6 are the most common. In forming such compounds, each molecule or atom donates a pair of electrons to the metallic atom, forming a semi-covalent type of bond. Thus, in the nitrocobaltates, six nitro groups each donate a pair of electrons to a cobalt(III) ion, forming the complex ion.



In the positive triammine cobalt(III) ion, three ammonia molecules donate one pair of electrons each to the cobalt(III) ion, to form the complex ion.



The covalent character of the coordination bond is evident from the fact that both the ions and the molecules that form it fail to exhibit their characteristic reactions after coordination.

Included in the coordination compounds are the double salts, the complex salts, the oxysalts, and the hydrates.

See also **Chelates and Chelation**; **Cobalt**; **Copper**; **Gold**; **Hydrate**; **Iron**; **Manganese**; and **Molybdenum (In Biological Systems)**.

COORDINATION NUMBER. The number of nearest neighbors of a given atom in a crystal structure. In covalent crystals, only those neighbors to which the atom is directly bonded are counted, and this number is usually 4 or less. In metals, the coordination number may be as high as 12, as in the close-packed structures.

COORDINATION POLYHEDRA. The arrangement of oxygen ions about the cation to which they are closely bonded in an ionic crystal, as, for example, the group SiO_4 which forms a tetrahedron. Such polyhedra pack as units in the crystal structure.

COOT. See **Rails, Coots, and Cranes**.

COOTER *(Reptilia, Testudinata).* A turtle of the genus *Pseudemys*. The several species are found chiefly in the eastern and southern United States. Also called sliders.

COPAL. Copal is the hardened resin derived from several tropical trees. One of these, *Trachylobium hornemannianum*, is a large white-flowered tree of tropical east Africa. Another, *Hymenaea courbaril*, a tree with large white or purplish flowers, is a native of tropical South America.

The resin may be obtained from living trees, in which case it is a soft substance naturally slow to harden. In Zanzibar, copal resin occurs in fossil form, masses of resin closely resembling amber being dug from the ground. This is the best grade of copal, known as Zanzibar copal. Similarly, in South America the resin may be dug from the ground at the base of the tree, where it slowly accumulates. Copal is used in the making of high-grade varnishes. Of late it is being supplanted with synthetic cellulose lacquers. Several other trees also yield copal resin.

COPALITE (or Copaline). The mineral copalite or "Highgate resin" is a fossil resin found in irregular fragments in the blue clay of London, England. It resembles copal, the resin of certain modern tropical trees. Copalite is pale yellow to greenish or brownish, and emits an aromatic odor when broken. It has a hardness of 1.5; a specific gravity of 1.046; burns with a very smoky yellow flame.

COPE, EDWARD DRINKER (1840–1897). The son of a prosperous Philadelphia Quaker family, Cope was educated in Quaker schools. Cope taught at Haverford College, resigning in 1868 to take up the collection and description of fossils on a full-time basis. Using his personal fortune, Cope made a series of collecting trips to the American West throughout the 1870s, often in conjunction with the US Geological survey. His relationship with the survey was suspended in 1879 when his rival O. C. Marsh was appointed Chief Paleontologist of the Survey. Although Cope and Marsh collected vertebrate fossils from the same sites, Cope was the more prolific and gained scientific priority by publishing his findings first, eventually describing twice as many fossil remains as Marsh. The intense rivalry with Marsh for priority prompted Cope to purchase a controlling interest in the *American Naturalist* in 1878, which thereafter featured Cope's research and neo-Lamarckian theories. See also **Fossil Record**; **Marsh, Othniel Charles (1831–1899)**; and **Paleontology (The History)**.

Cope's research in the West led to the publication of two important works in paleontology: "The Vertebrata of the Cretaceous Formations of the West" (1875) and a companion "The Vertebrata of the Tertiary Formations of the West" (1884). Cope's impact on science was not limited to paleontology. A neo-Lamarckian, Cope reflected the dominant school of evolutionary thought in the United States in the latter part of the nineteenth century. His first important publication on evolution was "On the origin of genera" (1868). A believer in the inheritance of acquired characteristics, his kinetogenic theory held that the motion of an animal's limbs transformed the animal's moving parts. The new morphology, he argued, could be inherited by subsequent offspring. Believing that evolution worked more purposefully than Darwin suggested, he offered "Cope's rule" as evidence. This theory stated that all organisms evolved from smaller into larger forms over time. His ideas on evolution did not outlast him, and he was already on the defensive when he published *The Primary Factors of Organic Evolution* (1896) in a bid to refute Darwinism. See also **Lamarck, Jean–Baptiste Pierre Antoine de Monet de (1744–1829)**.

The last decade of Cope's life was fraught with difficulty. The rivalry between Cope and Marsh became a public spectacle after Cope campaigned to destroy Marsh's reputation in a newspaper exposé. In addition, misguided investments led to the loss of Cope's fortune in the late 1880s, forcing the sale of his large fossil collection to the American Museum of Natural History. Financial difficulty also led Cope to accept a teaching position at the University of Pennsylvania in 1889, which he held until his death.

COPEPODA. A subclass of small crustaceans. Some species are free-swimming and others live as parasites on fishes. The latter are called fish-lice.

COPOLYMER. See **Elastomers**; and **Polymerization**.

COPPER. [CAS: 7440-50-8] Chemical element, symbol Cu, at. no. 29, at. wt. 63.546, periodic table group 11, mp 1083 °C, bp 2567 °C, density 8.92 g/cm^3. Elemental copper has a face-centered cubic crystal structure. The metal is yellowish-red, soft, very malleable and ductile. Very thin sheet copper is translucent and transmits greenish-blue light. The element is unattacked by dry air, but in moist air containing CO_2, a protective greenish film of basic carbonate is formed. There are two natural isotopes, ^{63}Cu and ^{65}Cu. Seven radioactive isotopes have been identified, all with comparatively short half-lives: ^{58}Cu through ^{62}Cu, ^{64}Cu, ^{66}Cu, and ^{67}Cu. Copper may have been the first metal used by humans and today ranks second, exceeded only by iron, in annual consumption.

First ionization potential 7.723 eV; second, 20.29 eV; third, 29.5 eV. Oxidation potentials: $2Cu + 2OH^- \rightarrow Cu_2O + H_2O + 2e^-$, 0.361 V; $Cu + 2OH^- \rightarrow Cu(OH))_2 + 2e^-$, 0.224 V; $Cu^+ \rightarrow Cu^{2+} + e^-$, −0.153 V; $Cu \rightarrow Cu^{2+} + 2e^-$, −0.344 V; $Cu \rightarrow Cu^+ + e^-$, −0.522 V. Other important physical properties of copper are given under **Chemical Elements**.

Ancient Copper Metallurgy. Efforts by scientists to locate the sources of copper used in ancient Mediterranean and Near Eastern cultures through comparative chemical analyses of copper ores and archeological artifacts have largely failed for various mineralogical and metallurgical reasons. The isotopic composition of lead, an element present in a minor amount in many copper ores and bronze objects, is unchanged through metallurgical processes and may, in principle, be used to determine the sources of the copper used in Bronze Age artifacts. Results of work during the early 1980s suggest that for Late Bronze Age Crete the Laurion region in Attica, Greece, may have been a more important copper source than Cyprus.

In 1984, Lechtman (Massachusetts Institute of Technology Laboratory for Research on Archaeological Materials) reported that the metalsmiths of Andean cultures knew how to plate copper with gold or silver and how to treat alloys of copper, gold, and silver so that the surface of the metal consisted only of gold. The Spanish conquistadors, when melting gold and silver objects which had been looted from the Incas, found that the bullion was quite impure. Although appearing as pure gold or silver objects, the materials actually were alloys of those elements with copper. Andean metalsmiths had developed the alloys along with procedures for treating them so that the finished objects presented a surface of pure silver or pure gold. As further reported, the smiths also knew how to plate objects made entirely out of copper with a thin coating of gold or silver.

Readers interested in the archeology of copper will find several of the references listed at the end of this article of value. To assess the authenticity of ancient copper and bronze objects, museums such as the Cincinnati Art Museum have turned to modern scientific examination. For example, ultrahigh-voltage industrial computed tomography, coupled with x-ray inspection, has been used.

Copper Ores

Copper occurs as native copper, particularly in the region south of Lake Superior (often 99.9% Cu), as sulfides (chalcocite, copper glance, cuprous sulfide, Cu_2S; chalcopyrite, CuFeS), as oxide (cuprite, cuprous oxide, Cu_2O, red); as basic carbonates (malachite, $CuCO_3 \cdot Cu(OH)_2$, green; azurite, $2CuCO_3 \cdot Cu(OH)_2$, blue). The copper content of its ores varies from 0.3 to 8% Cu and the average is on the order of 2.5%. The value depends largely upon the content of silver and gold. The area of production is widely distributed; in the United States, Montana, Utah, New Mexico, Arizona, Michigan, and Tennessee.

Native copper ore is crushed, concentrated by washing with water, smelted, and cast into bars. Oxide and carbonate ores are treated with carbon in a smelter. Sulfide ore treatment is complex, but, in brief, consists of smelting to a matte of cuprous sulfide, ferrous sulfide, and silica, which molten matte is treated in a converter by the addition of lime and air is forced under pressure through the mass. The products are blister copper, ferrous calcium silicate slag, and SO_2. Refining is conducted by electrolysis, and the anode mud is treated to obtain the gold and silver. See Fig. 1.

Fig. 1. Beneficiation of basic minerals involves wet operations requiring large volumes of water. Here copper tailings from a mining operation are settled in a 275-foot (84-meter) diameter thickener which handles over 2000 gallons (76 hectoliters) per minute and some 13,000 tons (11,795 metric tons) of ore per day. Underflow solids are disposed of by pumping to tailing ponds. Clarified water is returned to the mill process, thus avoiding waste of water.

Leading world producers of copper include: United States, Chile, Canada, Zambia, Russia, Zaire, Peru, Philippines, South Africa, Australia, Japan, and China.

Copper is frequently detected in atmospheric particles, even in those collected at locations far removed from anthropogenic sources. Cattell and Scott (1978) reported similar enrichments found over the north Atlantic and the South Pole. It had been proposed that measured atmospheric concentrations are larger than those predicted for unenriched crustal weathering or oceanic production. It was proposed that the enrichment may result from natural processes of anomalously enriched elements in aerosol particles. These may derive from low- temperature volatilization processes, such as biological methylation, or volcanism, or direct sublimation from the earth's crust, or emissions from plants, or fractionating at the air-sea interface which enriches elements in particles produced from the oceans. Atmospheric studies conducted by Cattell and Scott near the island of Tasmania in 1977 led to the conclusion that a biogenic agent may be responsible for the approximately 20,000-fold enrichment of copper during aerosol production from the ocean.

Proposed Acid Injection Mining. In the early 1990s a new copper extraction technology, known as in situ leach mining, was under investigation. This methodology was proposed, and demonstration plants were to be constructed to test the proposal. These were jointly sponsored projects by the U.S. Bureau of Mines and two mining companies. If successful, leaching would cut the costs and hazards of the traditional open-pit methods currently used.

In this method a known copper deposit would be injected in several locations with a solution of dilute sulfuric acid. This acid would percolate through the veins of the ore-bearing rock (usually copper oxide). The copper would go into solution as copper sulfide and be pumped to the surface by way of several recovery wells. At the surface the copper would be plated onto cathodes (electrowinning process). It is proposed that the dilute solution, when free of copper, could be returned and circulated up to several times. An automatic analytical system would maintain the required strength of the acid solution. Proponents claim that the cost of the system would be less per ton of copper produced and would increase miner safety. One factor that must be carefully tested is the possible percolation of acid solution into nearby groundwater.

Special Properties

Copper is distinguished by several properties that contribute to its extensive use: (1) a combination of mechanical workability with corrosion resistance to many substances; (2) excellent electrical conductivity, (3) superior thermal conductivity; (4) effect as an ingredient of alloys to improve their physical and chemical properties; (5) efficiency of copper and some of its compounds as catalysts for several kinds of chemical reaction; (6) nonmagnetic characteristics, advantageous in electrical and magnetic apparatus; and (7) nonsparking characteristics, mandatory for tools for use in explosive atmospheres. There are additional attractions of copper for many other applications. The metal would be used even more widely, but for some uses, even though superior, copper cannot compete with substitute materials because of cost.

Unalloyed Copper. In the United States, the term *copper* signifies copper that contains less than 0.5% impurities or alloying elements. Copper-base alloys are those that contain no less than 40% copper. Additionally, copper appears as a minor, but important ingredient of several alloys. There are six major types of commercial, unalloyed copper. These are described briefly in Table 1.

TABLE 1. COMMERCIAL UNALLOYED COPPERS

Electrolytic Tough-Pitch Copper
Cu, 99.90%; O, 0.04% nominal; density 8.89–8.94 g/cm^3, EC, 101%
Architecture: downspouts, flashing, building fronts, gutters, screening, roofing
Automotive: radiators and gaskets
Electrical: conductive-wire contacts, terminals, switch parts, bus bars
Hardware: cotter pins, nails, rivets, soldering copper, ball floats
Other: anodes, chemical process equipment, kettles, pans, printing rolls, expansion plates, rotation bands, die-pressed forgings

Deoxidized Copper
Cu, 99.90% minimum; P, 0.025% nominal; density 8.94 g/cm^3, EC, 80–90%
Industrial: condensers, evaporators, heat-exchangers, dairy tubes, fraction-ating columns, kettles, pulp and paper piping, steam and water piping, tanks
Transportation: gasoline, oil, air, and hydraulic fluid lines, oil coolers
Other: shell rotation bands, die-pressed forgings, gauge lines

Oxygen-free Copper
Cu, 99.92% minimum; no residual oxidants; density 8.89–8.94 g/cm^3, EC, 101%
Electrical: conductors, electron tubes, bus bars, waveguides (for operation at high temperatures in presence of reducing gases)
Industrial: heaters, oil coolers, gasoline supply lines, radiators, refrigeration lines, water piping

Silver-bearing Copper
Cu, 99.90% minimum; 8–25 ounce (226–708 grams) Ag/ton; density 8.91 g/cm^3, EC, 100–101%
Electrical: commutator bars, heavy-duty motor windings (particularly for retention of strength at elevated temperatures)
Other: brazing solders, die-pressed forgings

Arsenical Copper
Cu, 99.68%, nominal; P, 0.025% nominal; As, 0.30% nominal; density 8.94 g/cm^3, EC, 90%
Industrial: heat-exchangers, boilers, radiators, condenser tubes

Free-cutting Copper
Cu, 99.4–99.5%: Te, 0.5–0.6%: density 8.94 g/cm^3, EC, 90%
Industrial: electrical connectors, motor and switch parts, soldering coppers, screw-machine parts, forgings, welding-torch tips

EC, electrical conductivity (International Annealed Copper Standard)

Very-High-Copper Alloys. Although not meeting the foregoing definition of copper precisely, there is a group of copper alloys which contain only a few percent of other ingredients and commonly these are also referred to as coppers, usually with the name of the other element preceding copper in the name — as *chromium copper* or *beryllium copper*. These very-high-copper alloys are described briefly in Table 2.

Because of major changes made in the production of electronic circuits, including surface-mount technology and the use of smaller, lighter,

TABLE 2. VERY-HIGH-COPPER ALLOYS

Cadmium Copper
Cu, 99.00-plus %; Cd, 0.6–1.0%
Cadmium toughens copper and increases resistance to fatigue: also increases softening temperature.
Electrical conductivity (fully annealed) is about 95% (IACS).
Essentially free of oxygen; not susceptible to gassing.
Uses: contact wires used in electrical transportation, notably long-span overhead electric transmission lines.

Chromium Copper
Cu, 99.50%; Cr, 0.5%
Chromium improves mechanical properties while retaining high thermal and electrical conductivities.
Strength and hardness depend on heat treatment and not cold working — hence alloy can be used up to temperature of about 450 °C without danger of softening.

Tellurium Copper
Cu, 99.50%; Te, 0.5%
Tellurium increases softening temperature of work-hardened copper.
Alloy is excellent where combination of good machinability and electrical conductivity is required.
Uses: motor and switch parts, electrical connectors, screw-machine parts, electrical instrument parts.

Beryllium Copper
Type 1: Cu, 98%; Be, 2%
Type 2: Cu, 97%; Be, 0.4%; Co, 2.6%
Cobalt is added as a lower-cost substitute for beryllium.
Uses: instrument springs, bellows, diaphragms, bourdon tubes, nonsparking sparking tools for hazardous locations.
Alloy permits springs to be shaped while soft, followed by hardening.
Selenium copper also available for combining high electrical conductivity with free-machining and hot-working properties. Alloy makes excellent copper-to-glass seals.

higher-density components, interconnection design requirements have become more stringent. Higher-density electronic packaging increases the demands for improved electrical, mechanical, and thermal characteristics of connector materials. To meet some of these needs, there has been increasing demand for beryllium-copper strips in many instances to replace brass alloys and phosphor bronzes.

Copper also is finding increased applications in composite materials, notably graphite/Cu. These composites provide both weight savings and greater strength and stiffness in advanced aerospace applications.

Growing interest also is being shown in copper-nickel-tin alloys that can be aged hardened after forming. These alloys have improved tensile strength and greater resistance to oxidation, stress relaxation, fatigue, and stress-corrosion cracking. They are finding increased usage in electronic leads, contact pins, and sockets, as well as for eyeglass frames, circuit boards, and electronic-contact clips.

In an effort to avoid penalties pertaining to lead in potable-water plumbing systems, pipe fitting and fixture manufacturers are turning away from the free-cutting copper alloys that contain lead. Copper alloyed with nontoxic bismuth and a ductility enhancer, such as phosphorus, indium, and tin, which machine as well as leaded material, are now being considered. Most possible copper alloying combinations are now under study. This program is carefully detailed in the Plewes-Loiacono reference cited.

The Brasses: There are eight principal categories of brasses, not including the leaded and alloy brasses. Brass essentially is an alloy of copper and zinc. Several of the brasses contain other ingredients, such as lead and iron. When zinc is added to copper, there is a progressive alteration of color and lowering of melting point. When the zinc content is about 10%, the metal is a bronze color; with 15% zinc, the color may be described as golden; from 20–40% zinc, there is a range of yellow colors; over 45% zinc, the color is silver-white. The melting point of a 95% copper-5% zinc brass is about 1,065 °C, whereas the melting point of 50% copper-50% zinc brazing metal drops to about 880 °C. The ratio of copper to zinc also progressively affects mechanical and corrosion-resistance properties. Maximum tensile strength, for example, is attained with a 55% copper content, whereas maximum ductility is attained with a 70% copper content. This exceptional range of properties accounts for the availability and demand for a wide variety of brasses. Metallurgically, brasses may be classified as (1) *alpha brass*, in which the content of zinc is less than 36% and in which the zinc is dissolved in the copper, imparting to the alloy the basic structure of copper; (2) *beta brass*, in which the content of zinc ranges between 36% and 45%. This alloy contains the CuZn as a compound and enhances the hot workability of the alloy; and (3) *gamma brass*, in which the zinc content exceeds 45% and where there are crystals in the alloy. This combination does not lend itself to either hot or cold workability. Some of the important commercial brasses are described briefly in Table 3.

The Bronzes: Classically, a bronze is defined as an alloy of copper and tin, but over the years the term has taken on a much broader meaning. The term may apply to numerous copper alloys that possess a crystalline, bronze-like structure, are of a bronze color, or may contain some tin. Further, bronze generally is considered a casting metal. In contrast, brass is generally wrought. Some alloys are commercially named bronze even though they contain no tin whatsoever.

Copper Wire and Cable: *The International Annealed Copper Standard* (IACS), which sets annealed copper as having 100% electrical conductivity as a basis against which to compare other metals, alloys, and materials, is accepted internationally. Using this standard for comparison, the conductivity of copper is exceeded only by silver for which the IACS figure is 108.4%. This comparison is on the basis of conductivity per gram, pound, or other mass unit. Aluminum, although widely used as an electrical conductor for selected applications, has a rating on this schedule of approximately 61%, steel a rating of 11%, and nickel-chromium alloy (valued because of its high electrical resistance rather than conductivity) has a rating of 1.5%. Thus, the value of copper for electrical conductors, considering its availability and economics, is self-evident.

Processing Equipment: In terms of thermal conductivity, assigning a value of 100 to copper, the metal is exceeded only by silver which has a value of 108. Copper is followed by gold (76), aluminum (56), magnesium (41), zinc (29), nickel (15), iron (15), steel (13–17), lead (9), and antimony (5). Thermal conductivity means good heat transfer and this is extremely important in most industrial processing equipment where heating and cooling cycles are involved. This property, when combined with corrosion resistance, makes copper attractive for the construction and lining of process vessels. Deoxidized copper, admiralty brass, and arsenical copper are effective in condenser tubes operating with fresh water. Copper is less suitable for seawater because of its inability to form a protective film. Aluminum brass and 70–30 cupronickel alloy are favored for severe seawater service. Copper and copper alloys are not suited for use in oxidizing acidic solutions, in mercury, or in the presence of free NH3. Copper vessels are used extensively in food processing and for numerous organic materials, particularly distillation columns and hardware. The relatively high cost of copper as compared with other metals, however, is always an important factor.

Piping: Copper and copper alloys are used in a wide variety of pipes and tubes, both for industrial and domestic systems. In many areas, galvanized water pipe has been almost completely replaced by copper piping in new construction. Advantages include corrosion resistance and ease of installation, which offset higher costs. Because of excellent thermal conductivity, copper and brass fittings are used widely in hot water and steam-heating systems. However, the greater conductivity of bare copper pipe in long runs requires more attention to insulation covering.

Chemistry and Compounds: Copper is dissolved best by HNO_3; not attacked by cold dilute HCl or H_2SO_4, but in hot HCl dissolves to yield cuprous chloride, in hot concentrated H_2SO_4 to yield copper sulfate; attacked by chlorine, especially when heated, to form cuprous and cupric chlorides; only slight action by H_2S or SO_2 at ordinary temperatures in the absence of air.

In view of its $3d^{10}4s^1$ electron configuration and the relatively small energy difference between the two levels, copper forms dipositive ions as well as monopositive ones. In fact, the former are the more stable in aqueous solution, due primarily to the larger heat of hydration of Cu^{2+} than Cu^{+} Moreover, the *d*-electrons may participate in bonding, and tripositive copper, Cu(III), appears in complexes. In addition, copper forms a number of compounds essentially covalent in character, such as copper(I) oxide, Cu_2O.

This compound is less stable at room temperature than copper(II) oxide, CuO, although Cu_2O occurs in nature (as cuprite). It is the stable oxide above 1.026 °C. It is prepared by fusion of copper(I) chloride, CuCl with sodium carbonate, Na_2CO_3. In its crystal, each copper atom has two colinear bonds, and each oxygen atom four tetrahedral ones; two

TABLE 3. REPRESENTATIVE BRASSES AND BRONZES

Gilding Brass
Cu, 95%; Zn. 5%; Pb, 0.03% maximum; Fe, 0.05% maximum; density 8.86 g/cm^3; mp 1066 °C; AT, 427–788 °C; HWT, 760–871 °C
Coinage: coins, metals, tokens
Munitions: firing-pin support shells, bullet jackets, fuse caps, primers
Novelties: emblems, plaques, jewelry
Other: base for gold plate and for vitreous enamel

Commercial Bronze
Cu, 90%; Zn, 10%; Pb, 0.05% maximum; Fe, 0.05% maximum; density 8.80 g/cm3; mp 1043 °C; AT, 427–788 °C; HWT, 760–871 °C
Architectural: grillwork, etching bronze, screen cloth, weather stripping
Cosmetics: lipstick cases, compacts
Hardware: kickplates, line clamps, marine hardware, escutcheons, rivets, screws
Munitions: rotating bands, primer caps
Other: costume jewelry, screen wire, ornamental trim, vitreous enamel base

Red Brass
Cu, 85%; Zn, 15%; Pb, 0.06% maximum, Fe, 0.05% maximum; density 8.75 g/cm^3; mp 1027 °C; AT, 427–732 °C; HWT, 788–900 °C
Architectural: trim, etching parts, weather stripping
Electrical: screw shells, sockets, conduit
Hardware: fasteners, fire extinguishers, eyelets
Industrial: heat-exchanger tubes, condensers, flexible hose, piping, pumps, radiator cores, pickling crates
Other: compacts, costume jewelry, dials, badges, etched articles, lipstick cases

Jewelry Bronze
Cu, 87.5%; Zn, 12.5%; Pb, 0.05% maximum; Fe, 0.10% maximum; density 8.78 g/cm^3; mp 1035 °C; AT, 427–760 °C; HWT, 760–900 °C
Architectural: angles, channels
Hardware: chains, fasteners, slide fasteners, eyelets
Novelties: costume jewelry, emblems, compacts, etched articles, lipstick cases, plaques
Other: base for gold plate

Low Brass
Cu, 80%; Zn, 20%; Pb, 0.05% maximum; Fe, 0.05% maximum; density 8.67 g/cm^3; mp 999 °C; AT, 427–704 °C; HWT, 816–900 °C
Architectural: medallions, spandrels, ornamental metalwork
Electrical: battery caps
Instruments: bellows and musical instruments
Hardware: flexible hose, pump lines, tokens, clock dials

Cartridge Brass
Cu, 70%; Zn, 29-plus %; P, 0.07% maximum; Fe, 0.05% maximum; density 8.53 g/cm3; mp 954 °C; AT, 427–760 °C; HWT, 732–843 °C
Automotive: radiator cores and tanks, reflectors
Electrical: flashlight shells, lamp fixtures, socket shells, screw shells, bead chain
Hardware: fasteners, pins, rivets, eyelets, springs, tubes, stampings
Munitions: various components. Note: Admiralty brass is similar: Cu, 71%; Zn, 28%; Sn, 1%

Yellow Brass
Cu, 65%; Zn, 34-plus %; Pb, 0.15% maximum; Fe, 0.05% maximum; density 8.47 g/cm^3; mp 932 °C; AT, 427–704 °C

Architectural: grillwork
Automotive: reflectors, radiator cores and tanks
Electrical: lamp fixtures, flashlight shells, screw shells, socket shells, bead chain
Hardware: kickplates, push plates, locks, hinges, grummets, fasteners, eyelets, stencils, plumbing accessories, pins, rivets, screws, springs

Muntz Metal
Cu, 60%; Zn, 39-plus %; Pb, 0.30% maximum; Fe, 0.07% maximum; density 8.39 g/cm3; mp 904 °C; AT, 427–593 °C; HWT, 621–788 °C
Hardware: large nuts and bolts, brazing rod, condenser plates, valve stems, hot forgings

Leaded Brasses
When lead is added to brass up to about 4%, improved machinability results. The lead has practically no effect on tensile strength or hardness. However, for cold-worked materials, lead does lower ductility and shear strength.

Phosphor Bronzes
Although tin is the primary alloying element in these alloys, their name derives from the addition of small quantities of phosphorus used as a deoxidizing agent in casting the alloys. Tensile strength ranges from moderate to very high, decreasing with amount of tin added. Tin percentage will range from 1.25 to 10%. Of the copper alloys, the phosphor bronzes are best suited for sea duty and where acid reagents may be present.

Silicon Bronzes
Most of these alloys are of proprietary compositions and are known by a variety of trade names. Silicon content ranges from 1.5 to 3.5%; usually less than 1.5% zinc content. Tin, manganese, and iron also may be added in small quantities. Because of their excellent strength, ease of welding, and corrosion resistance, the alloys have become important construction materials. As the silicon content increases, the alloys become more subject to fire cracking.

Aluminum Bronzes
The aluminum content of these alloys ranges from 4 to 10%. They are moderately hard, very ductile, and tough. The alloys resist scaling and oxidation at high temperatures because of the aluminum content. They perform well in both acids and alkalis. The alloys are good for sea duty, particularly in contact with turbulent seawater.

Nickel Silvers
Nickel essentially is added to copper-zinc alloys to enhance color. With a nickel content of about 18%, the alloy is silver-white. Also, most of the mechanical properties and corrosion resistance are improved. The alloys find wide application for operations that require ductility in the cold condition, as in stamping, spinning, deep drawing, and for articles to be plated. An alloy widely used as a spring material because of its high tensile and fatigue properties has the composition: Cu, 55%; Zn, 27%; Ni, 18%. German silver contains: Cu, 50%; Ni, 30%; Zn, 20%. It is interesting to note that the nickel silvers do not contain silver.

Cupronickels
The nickel silvers generally are classified as brasses. Cupronickels fall more into basic copper-nickel alloys. Possible minor ingredients are manganese, iron, and zinc. These alloys can be used for severe drawing, spinning, and stamping operations because they do not harden readily. They also are extensively used for condenser tubes and plates, heat exchangers, and other process equipment.

AT, annealing temperature range.
HWT, hot-working temperature range.

such interpenetrating lattices constitute the structure. Copper(I) hydroxide, CuOH, is relatively stable, and is produced by electrolysis of a sodium chloride solution between copper electrodes (by action of NaOH on the cathode). Copper(II) oxide, produced by heating copper in air, is also essentially covalent (Cu−O, 1.95 Å); it has tetrahedral bonding of the oxygen atoms, and coplanar bonding of the copper atoms. Copper(II) hydroxide, is precipitated by alkali hydroxides from Cu^{2+} solutions. It is gelatinous, and its composition and solubility vary somewhat with the alkali concentration. It is thermodynamically unstable even in contact with liquid water with respect to dehydration to CuO, but this occurs only very slowly, except upon heating or when catalyzed by hypochlorite, hydrogen peroxide, etc.

Copper(I) halides are formed with chlorine, bromine and iodine, the chloride and bromide by reduction of the copper(II) halides with copper powder, and the iodide by reduction of copper(II) sulfate, $CuSO_4$ solution with potassium iodide. The fluoride appears never to have been made, despite reports to the contrary. All are insoluble in H_2O. Copper(II) fluoride, CuF_2 may be made from CuO and hydrofluoric acid at 400 °C, copper(II) chloride, $CuCl_2$ by dissolving the oxide or carbonate in HCl, and copper(II) bromide, $CuBr_2$ from copper and bromine water; copper(II) iodide, CuI_2, is unstable at room temperature with respect to decomposition into CuI and iodine. The chloride and bromide are water-soluble, and ionic. The fluoride is only slightly water-soluble. Anhydrous copper(II) chloride, $CuCl_2$, is monoclinic and its structure contains infinite-chain molecules formed by $CuCl_4$ groups that share opposite edges. $CuBr_2$ has a similar structure.

Complex halides of both monovalent and divalent copper are known. The monovalent complexes are primarily of the composition $MCuX_2$, where X is a halogen atom and M usually an alkali metal, although $CuCl_3^{2-}$ ions are also known, being found in infinite chain $(CuCl_3^{2-})_n$ structures, as in crystals of Cs_2CuCl_3. The ion $CuCl_4^{3-}$ is also known. The composition of the copper(II) complex halides is primarily in terms of

$CuCl_3^-$, $CuCl_4^{2-}$, or $CuBr_4^{2-}$, ions, although the corresponding complex fluoride has trivalent copper, as in K_3CuF_6. Its paramagnetic moment indicates two unpaired electrons.

Copper oxyhalides of a number of different compositions have been reported, but the most definitely established compositions are Cu(OH)Cl, $Cu_2(OH)_2Cl_2$, and $CuBr_2 \cdot 2Cu(OH)_2$. The property of forming basic salts is not limited to the halides of copper. Basic sulfates, such as $CuSO_4 \cdot 2Cu(OH)_2$, $CuSO_4 \cdot 3Cu(OH)_2$, $CuSO_4 \cdot 4Cu(OH)_2$, and $CuSO_4 \cdot 5Cu(OH)_2$, have been prepared, more or less hydrated. In copper(II) carbonate, the stable forms are oxycarbonates, $x CuCO_3 \cdot y Cu(OH_2)$, (where the *x:y* ratios may be 2:1, 1:1, 2:3, 1:9, and still other values. Many of these compositions occur in minerals, such as malachite and azurite. Copper forms complexes with larger number of ions and molecules. The halogen complexes were discussed above. In general, copper tends to be 6-coordinate, as in the complex ion $[Cu(H_2O)_2 \text{ethylenediamine})_2]^{2+}$. With NH_3 and many amines, stable complexes are formed, both of Cu^+, such as $[Cu(NH_3)_2]^+$, and of Cu^{2+}, such as $[Cu(NH_3)_4]^{2+}$ which add halogen, pseudohalogen, and many other anions to form compounds of the composition $Cu(NH_3)_2X_2$ and $Cu(NH_3)_4X_2$.

Among the other copper compounds, copper(II) acetate is used as a pigment and fungicide; in its basic form it is the familiar verdigris that forms on copper surfaces in the presence of moisture and organic matter. The arsenic compounds of copper are used as insecticides and wood preservatives: copper(II) arsenite is called "Scheele's green" and copper(II) acetoarsenite, $Cu(AsO_2)_2 \cdot Cu(C_2H_3O_2)_2$, is "Paris green." Copper(II) hexacyanoferrate(II), brown, is precipitated from copper(II) solutions by soluble hexacyanoferrates(II), even from very dilute solutions, and copper(II) sulfide, black, by H_2S or other soluble sulfides. Copper(II) sulfate, when hydrated, forms its characteristic blue crystals (the hydrated Cu^{2+} ion is blue).

Copper(I) cyanide dissolves in alkali cyanide solution to form cyanocuprates(I) of the general formula $M_n[Cu(CN)_{n+1}]$ where M is an alkali metal, and n ranges in value from 1 to 5. Not all of the values, of course, are found for a particular alkali or in the presence of particular anions. With sodium cyanide, NaCN, most of the complex present has an n value of 2, but if the original solute was CuCl, more of the $n = 3$ cyanocuprate(I) is present. At low temperatures, values of n of 4 and 5 are found. Copper(II) appears to coordinate four cyanide ions to form the unstable tetracyanocuprate(II) ion which decomposes at once to the copper(I) complex and cyanogen. In fact, for Cu(II) the chelated complexes are more common than the simple ones, examples being those formed with ethylenediamine and its derivatives, oxalates, catechol, and the β-diketones.

A solution of CuCl in HCl absorbs carbon monoxide, forming copper(I) carbonyl chloride, $Cu(CO)Cl \cdot H_2O$. This reaction, which is used in gas analysis, is indicative of the ability of copper to combine with carbon monoxide. Evidence for a true carbonyl is limited to the observation that if hot carbon monoxide is passed over hot copper, a metallic mirror is produced in the hotter parts of the tube. Other organometallic compounds include the very unstable methyl copper, CH_3Cu, phenyl copper, C_6H_6Cu, and bischlorocopper acetylene $C_2H_2(CuCl)_2$.

Copper Industrial Chemicals: Copper oxides, salts, and organocopper compounds find extensive use in industry and commerce. Some of the more important compounds are summarized:

Cupric Acetate, [CAS: 142-71-2] $Cu(C_2H_3O_2)_2 \cdot H_2O$, sp gr 1.88, mp 115 °C, decomposes at 240 °C, dark-brown powder, slightly soluble in cold H_2O and alcohol; moderately soluble in hot H_2O and ether. Used as a fungicide, insecticide, as a catalyst, and in pigments.

Cupric Acetoarsenite [CAS: 12002-03-8] (Paris Green), $(CuOAs_2O_3)_3 \cdot Cu(C_2H_3O_2)_2$, emerald-green powder, very slightly soluble in cold H_2O, soluble in alcohol and potassium cyanide. Used as a wood preservative.

Cupric Acid Orthoarsenite [CAS: 10290-12-7] (Scheele's Green), $CuHAsO_2$, green powder, insoluble in H_2O, soluble in alcohol, acids, and NH_4OH. Used as a wood preservative.

Copper Carbonate (Basic), [CAS: 12069-69-1] $CuCO_3 \cdot Cu(OH)_2$, dark-green monoclinic crystals, insoluble in cold H_2O decomposes in hot H_2O, soluble in potassium cyanide. Malachite, a copper ore, is of this composition. Refined compound is used as a pigment.

Cupric Hydroxide, [CAS: 20427-59-2] $Cu(OH)_2$, blue, gelatinous compound, insoluble in cold H_2O decomposes in hot H_2O soluble in alcohol, NH_4OH, and potassium cyanide. Used as a pigment.

Cuprous Cyanide, [CAS: 544-92-3] $Cu_2(CN)_2$, white monoclinic crystals, insoluble in H_2O, soluble in HCl, NH_4OH, and potassium cyanide. Used in Sandmeyer's reaction to synthesize aryl cyanides.

Cuprous Iodide, [CAS: 7681-65-4] Cu_2O, cubic white crystals, practically insoluble in H_2O or alcohol, soluble in NH_4OH, potassium iodide, or potassium cyanide. Used in Sandmeyer's reaction to synthesize aryl chlorides.

Cupric Oxide, [CAS: 1317-38-0] CuO, black cubic crystals, insoluble in H_2O, soluble in HCl, NH_4OH, or ammonium chloride. Used as a green and blue colorant in ceramics.

Cuprous Oxide, [CAS: 1317-39-1] Cu_2O, red cubic crystals, insoluble in H_2O soluble in HCl, NH_4OH, or ammonium chloride. Cuprite, a copper ore, is of this composition. Refined compound is used in electrical rectifiers.

Cupric Sulfate, [CAS: 7758-99-8] (pentahydrate), [CAS: 7758-98-7] (anhydrous), $CuSO_4 \cdot 5H_2O$, blue triclinic crystals, moderately soluble in cold H_2O, quite soluble in hot H_2O, very slightly soluble in alcohol. Used in copper plating, dyestuff manufacture, water treatment, germicides, and coppering of steels.

Cupric Chloride, [CAS: 7447-39-4] $CuCl_2$, brown-yellow powder, quite soluble in cold H_2O or alcohol, very soluble in hot H_2O. Catalyst for several organic syntheses, including production of vinyl chloride monomer.

COPPER AGE. An archeological term to designate a cultural level that has been discerned between the Bronze Age and Iron Age. It is characterized by use of copper for weapons and tools.

COPPER (In Biological Systems). The activity of copper in plant metabolism manifests itself in two forms: (1) synthesis of chlorophyll, and (2) activity of enzymes. In leaves, most of the copper occurs in close association with chlorophyll, but little is known of its role in chlorophyll synthesis, other than the presence of copper is required. Copper is a definite constituent of several enzymes catalyzing oxidation-reduction reactions (oxidases), in which the activity is believed to be due to the shuttling of copper between the $+1$ and $+2$ oxidation states.

Traces of copper are required for the growth and reproduction of lower plant forms, such as algae and fungi, although larger amounts are toxic.

The effects of copper deficiency in plants are varied and include: die-back, inability to produce seed, chlorosis, and reduced photosynthetic activity. In contrast, excesses of copper in the soil are toxic, as in the application of soluble copper salts to foliage. For this reason, copper fungicides are formulated with a relatively insoluble copper compound. Their toxicity to fungi arises from the fact that the latter produce compounds, primarily hydroxy and amino acids, which can dissolve the copper compounds from the fungicide.

Copper is a necessary trace element in animal metabolism. The human adult requirement is 2 milligrams per day, and the adult human body contains 100–150 milligrams of copper, the greatest concentrations existing in the liver and bones. Blood contains a number of copper proteins, and copper is known to be necessary for the synthesis of hemoglobin, although there is no copper in the hemoglobin molecule.

Anemia can be induced in animals on a low copper diet, such as milk, and appears to be due to an impaired ability of the body to absorb iron. This anemia, however, is rare, because of the widespread occurrence of copper in foods. In locations, such as Australia and the Netherlands, diseases of cattle and sheep, involving diarrhea, anemia and nervous disorders, can be traced either to a lack of copper in the diet, or to excessive amounts of molybdenum, which inhibits the storage of copper in the liver.

Ingestion of copper sulfate by humans causes vomiting, cramps, convulsions, and as little as 27 grams of the compound may cause death. An important part of the toxicity of copper to both plants and animals is probably due to its combination with thiol groups of certain enzymes, thereby inactivating them. The effects of chronic exposure to copper in animals are cirrhosis of the liver, failure of growth, and jaundice.

Copper deficiency in plants is most frequent on organic soils, such as newly drained bogs, and on very sandy soils. The severe copper deficiency often found when bogs and marshes are first used for crop production is called *reclamation disease* in some parts of the world.

Ruminants are sensitive to copper deficiency. The symptoms of copper deficiency in animals vary with the species and age, but often the fading of brown or black hair is evident. On some acidic soils, the use of copper in fertilizers increases crop and pasture production, and the increases in level of copper in the plants help to prevent copper deficiency in the cattle and sheep. In parts of Australia, livestock production was impossible until copper fertilizers were used on the pastures. Application of copper fertilizers to alkaline soils generally does not increase the copper level in the crop. Farm animals are often supplied with copper in the form of dietary mineral supplements. Compounds used include copper gluconate, copper oxide, and copper sulfate.

Although copper fertilizers will sometimes increase crop yields and improve the nutritional quality of the crops, this practice must be used with caution and only on copper-deficient soils. Both plants and animals are subject to toxicity from excessive levels of copper. Ruminants, especially sheep, are sensitive to copper toxicity as well as to copper deficiency. Adding a copper fertilizer to a soil that naturally contains rather high levels of available copper may increase levels of the metal in the forage to the point of causing copper toxicity in grazing sheep. Copper toxicity from soils naturally high in copper occurs in Australia, but is uncommon in the United States. There are soils in the United States, however, that produce forage levels of copper close to toxicity limits, and if copper-bearing mineral supplements are inadvertently used with these forages, copper toxicity to sheep may result.

It is not easy to set a definite limit, in terms of the copper concentration in the diet, that will permit accurate predictions of the danger of copper deficiency or of copper toxicity in cattle and sheep. In particular, if the molybdenum concentration in the forage is high, extra amounts of copper are needed to prevent deficiency. Also, higher copper levels can be tolerated without danger of toxicity with molybdenum present.

Monogastric animals, including humans, are less sensitive than ruminants to either copper deficiency or toxicity. Copper deficiency in people has been found only when other complications, such as excessive bleeding, general starvation, and iron deficiency, are also present. Wilson's disease, an inherited disease of humans, prevents the loss of excess copper from the body and brings on copper toxicity. No direct relationships have been found between levels of available copper in the soil and the copper status of humans.

A number of copper-containing protein compounds are enzymes with an oxidase function (ascorbic acid oxidase, urease, etc.) and these play an important role in the biological oxidation-reduction system. There is a definite relationship of copper with iron in connection with utilization of iron in hemoglobin function.

Copper absorption is depressed by ascorbic acid, dietary phytates, cadmium, mercury, silver, and zinc. It appears that metals impede copper absorption through competition for metal-binding sites. Dietary copper, molybdenum, and sulfur are closely interrelated in optimum copper and molybdenum nutrition of ruminants. Increase pasture molybdenum content and low-pasture copper result in a condition known as "peat scours."

Copper toxicity tends to accumulate in the liver. The capacity to tolerate copper varies considerably with the species. Sheep are most susceptible. Swine have a much greater tolerance and copper may be added to the swine diet for pharmacological reasons (for example, use as an anthelminthic to control internal parasites).

Continuing research is providing a better understanding of the biological role of copper. The prooxidant and antioxidant effects of ascorbic acid and metal salts, including copper, in a beta-carotene-linoleate model system were studied by Israeli scientists. The interacting effects of ascorbic acid and metal ions on carotene oxidation were studied in an aqueous carotene-linoleate solution at pH of 7. Ascorbic acid at concentrations up to 10^{-3} M was a prooxidant. Fe^{3+} and, to a lesser extent, Co^{2+} acted synergistically with ascorbic acid, the prooxidant effect increasing with metal concentration. Cu^{2+} formed a prooxidant system with ascorbic acid only at low metal concentration, but as the copper concentration was raised, inversion of activity occurred and the copper-ascorbic acid system exerted a stabilizing action on carotene. Prooxidant effects were enhanced and antioxidant effects weakened in the presence of added linoleate hydroperoxides. The latter were unstable in the presence of ascorbic acid and especially ascorbic acid plus Cu^{2+}. Ascorbic acid itself became unstable in the presence of Cu^{2+}. Oxygen depletion, brought about by the rapid oxidation of ascorbic acid, may be partly responsible for the carotene-stabilizing effect of the Cu^{2+} couple. The investigators postulated that additional stabilization results from the radical-scavenging properties of copper or of a copper chelate formed by ascorbic and/or dehydroascorbic acid.

A team of investigators at the Department of Food Science and Human Nutrition, Michigan State University, studied the kinetics of ascorbic acid stability of tomato juice as a function of temperature, pH, and metal catalyst, including copper. The rate of copper-catalyzed destruction of ascorbic acid increased as copper concentration in tomato juice increased, and was affected by pH.

Relatively recent hypotheses concerning the effect of zinc-to-copper ratios in the diet as a determining factor of plasma cholesterol levels have been made.

A study by the Department of Foods and Nutrition, Kansas State University is exemplary of the much needed further research in determining the properties of certain elements, including copper, when contained in various food substances. Part of the study was directed at determining the effects of cooking on copper content of turkey muscle. The researchers found that copper was significantly lower in cooked than in raw breast turkey muscle, but similar in raw and cooked thigh muscle.

COPPER LOSS. This term is frequently used to denote the resistance loss in the conductors of electrical circuits or machines. In most machines there are two types of electrical losses, those caused by winding resistance, i.e., the copper loss, and those caused by the magnetic core, i.e., core loss. Copper loss is given by

$$P = I^2R$$

where I is the current (effective value for A.C.) and R the resistance.

COPULATION. The act of sexual union by which the seminal fluid, containing the reproductive cells of the male, is transferred to the genital passages of the female.

The germ cells are adapted for locomotion through liquids, hence many aquatic species need only discharge them into the surrounding water simultaneously to enable them to come together for fertilization. If the egg is to develop in the body of the mother, however, or if the animal is entirely terrestrial, the liquid medium in which fertilization occurs is secreted by the body and a direct transfer from male to female is usually necessary. Artificial insemination of animals has been accomplished.

In some animals copulation is accomplished merely by the apposition of the orifices of the genital ducts, but in most cases the terminal portion of the female organs becomes a vagina for the reception of a male intromittent organ. This organ varies greatly. In some of the rotifers the pointed end of the body serves for the introduction of the germinal material, although some have a special projecting organ called the penis. Some of the roundworms have a pair of copulatory setae, which project from the alimentary tract. In the crustaceans certain paired appendages are modified for introduction into the female and in the spiders the male discharges the seminal fluid onto a web and takes it up into his palpi, which are modified for the transmission of the material to the female ducts.

Among the vertebrates most intromittent organs are in the form of a penis developed either as a projecting fold in the wall of the cloaca or as a protrusible organ associated with the urogenital passages at their caudal extremity. In the shark the pelvic fins sometimes bear lobes which are thrust into the cloaca of the female during copulation.

In humans, the terms *sexual act* and *sexual intercourse* are also used. For conception to occur, intercourse must occur during the woman's fertile period, at a time close to ovulation. Generally, this time occurs at the midpoint between successive menstrual periods.

COQUINA. This is a Spanish word meaning little shells. It is a coarse and highly porous limestone made up of shells and shell fragments loosely cemented. It is being formed at present along the coasts of Florida, where it is frequently referred to as "beach rock." Only a few of the limestone formations of former geological periods are true coquina. In Bermuda coquina, largely of Aeolian origin, is sawed into blocks and used as a building material.

CORACIIFORMES *(Aves).* This order consists of the superfamilies kingfishers, todies, motmots, with families of bee-eaters, cuckoo-rollers, rollers, hoopoes, wood hoopoes, and hornbills. Only a few common structural characteristics and habits unite the families of this order; as a result, this order was previously subject to many different decisions concerning its relationship and position in the zoological system. Today, these birds have been combined into one order on the basis of their three partially fused anterior toes (syndactylism), because of their desmognathous palatal structure, their leg muscles, and because of particular plumage developments and arrangement. The feet are generally noticeably small. There are 2 notches in the rear edge on each side of the sternum (only 1 in hoopoes and hornbills), 10 primaries (often with a vestigial eleventh one), and 12 tail feathers (only 10 in motmots, hoopoes, and hornbills). The length is 9–105 centimeters ($3\frac{1}{2}$–41 inches). These are largely colorful tropical or subtropical land birds. The beak is often large and of peculiar shape. These birds are primarily meat, fish, and insect-eaters, although some also take fruit and berries. The young are naked and blind at hatching (with the exception of the hoopoes). The sexes are similar except in many of the hornbills and some kingfishers.

Most families are confined to the east of the Old World, but kingfishers are also found in the New World. Todies and motmots occur only in the New World. Bee-eaters, hoopoes, and hornbills probably originated in Africa, while the kingfishers originated in southeastern Asia. See Figs. 1 and 2.

CORAL *(Coelenterata).* The hard deposit built up by minute colonial animals called coral polyps that occur in the warmer oceans. The deposit consists principally of calcium carbonate. See Fig. 1.

The corals of the order *Hydrocorallinae* of the class *Hydrozoa* exist as sessile colonies with a massive encrusting or branching exoskeleton with pits in the surface from which the polyps arise.

The corals of the orders *Alcyonaria* and *Zoantharia* of the class *Anthozoa* (*Actinozoa*) are of different form and habits. Those of the alcyonarians are made up of minute spicules formed within the tissues, occasionally compacted in a hard central rod running through the entire colony and sometimes supplemented by an external covering. Red or precious coral is the hard axis of such a form and organ-pipe coral is made up of the connected tubes that once surrounded the living animals. Zoantharian corals build up hard deposits externally beneath the basal disk, which attaches them to the ocean floor. As new individuals arise from the edge of the living tissue their deposits become continuous with those already laid down and so large colonies produce extensive masses of coral rock. The form of these deposits varies. Some are slender and branching and others rounded and massive. They have received common names such as staghorn coral and brain coral.

Precious coral is secured principally in the Mediterranean and is the foundation of a considerable industry in Italy. Several thousands of persons in that country work coral into beads and other ornaments and make it into jewelry.

The formation of coral islands in the warmer oceans has resulted in many habitable land masses, and in the same waters submerged reefs of this material are serious obstacles to navigation.

CORAL REEF. A complex, ecological association of benthonic (bottom-living) and attached, calcareous, shelly marine invertebrates, forming either fringing reefs, barrier reefs, or atolls. The lagoons of barrier reefs and atolls are important loci for the deposition of fine-grained calcium carbonate mud called drewite. Fossil reefs include all types of organic reefs which show a distinct ecological and structural evolution from the

earliest known fossiliferous limestones to the typical atolls of the South Pacific Oceanic Islands. See Fig. 1.

The Great Barrier Reef

Coral reefs and rain forests, both striking features of tropical latitudes, are two of the most productive, most species-rich ecosystems on earth. The Great Barrier Reef is the largest system of corals and associated life forms anywhere in the world. It is encompassed in a Marine Park within the Great Barrier Reef region, convering an area of about 350,000 square kilometers on the Australian continental shelf — larger than the land mass of the United Kingdom. The reef stretches for more than 2000 km along the northeastern coast of Queensland in a complex maze of approximately 2600 individual reefs, ranging in area from less than 1 hectare (2.5 acres) to more than 100 square km. In the north, the reef is narrow and its eastern edge is marked by a series of narrow "ribbon" reefs, but in southern areas it broadens out and presents a vast wildnerness of "patch" reefs, many in the shape of a boomerang.

As delineated by Kelleher (1986), the reef is diverse not only in the form and size of its individual reefs and islands, but in its inhabitants. Six species of turtle occur in the region and there is an estimated total of 1500 or more species of fishes present in the reef region. The reef may be the last place on earth in which the dugong (*Dugong dugon*, an endangered species) ranges in abundance and thus far has not been threatened in that area.

The Great Barrier Reef has been a focal point of scientific research for many years. Although the reef is an immense tourist attraction, the Australian Ministry for Science has undertaken numerous wise and prudent measures to protect and preserve the region and still make it a welcome place for persons with various kinds of interest to visit and enjoy. The Australian government some years ago established the Great Barrier Reef Marine Park Authority (GBRMPA). Townsville, a city on the Australian mainland and approximately midway between the northern and southern reaches of the Great Barrier Reef, is the site of numerous reef-related research efforts and a meeting point for various researchers, as for example the 1988 Sixth International Coral Reef Congress.

The Summer 1986 issue of *Oceanus*, **29**(2) (the American-Australian Bicentennial Issue) contains several expertly written and illustrated descriptions of a wide variety of scientific interest pertaining to the Great Barrier Reef. Only a few highlights can be reviewed here.

Origins of the Reef. As pointed out by Hopley and Davies[1] (1986), the first effective attempts to study the origin of the reef were made in 1926 when holes were drilled to 183 meters at Michaelmas Cay in the northern reef region. In 1934, holes were drilled on Heron Island in the south to a depth of 223 meters. At the time, these bores were considered disappointing as they did not achieve the intended objective of proving that Darwin's subsidence theory of coral reefs was applicable to the Great Barrier Reef. This objective clouded the interpretation of much crucial data in the cores.

Both holes bottomed in sands, but their significance was ignored as Darwin's theory demanded volcanics. The reef was, therefore, thought to occur below the sands. The drill core from both holes indicated the presence of unconformities detectable on the basis of observation as well as geochemical data. The current accepted possibility of reef growth in superincumbent positions, many times producing what are now seen as unconformities related to sea level changes, was not previously recognized.

The initiation of the Great Barrier Reef is now believed to be related to the more recently developed concept of continental drift and seafloor spreading. See article on **Earthquakes, Seismology, and Plate Tectonics**. It is estimated that until about 75 million years ago, Australia and Antarctica were joined. Most of Australia lay south of 40 °S, far from waters warm enough for coral growth. About 65 million years ago, it is estimated that Australia began to split from Antarctica and move northward. Subsequently, northeastern Australia was formed by rifting between the Australian and Pacific plates and, by the time a Continental Shelf had formed, northern Australia lay close to 30 °S latitude. Uplift, rifting, and volcanism produced a complex rift basin system that has controlled the location and form of the Continental Shelf.

Hopley and Davies also stress that as Australia continued to move north, the first development of ice in Antarctica caused worldwide falls in sea level. Recent seismic investigations have shown that shelf evolution was dominated by fluvial sediment yield (current annual sediment input from North Queensland rivers alone is estimated at 28 million tons). Thus, the relative height of sea level provided the principal control of development. This was illustrated by Symond, Davies, and Parisi in 1983. See Fig. 2.

During periods of low sea level, alluvial processes affected the shelf. At the shelf edge, fluvial and wave-dominated deltaic progradation (a seaward advance of the shelf resulting from the nearshore deposition of sediments brought to the sea by rivers) took place into deeper water. During the high sea-level phases, sedimentation was generally restricted to coastal deltaic progradation into the shallow water of the inner shelf and onlap of the continental slope by submarine fans together with extensive upper slope erosion. It is estimated that this main phase of shelf construction from the late Oligocene to the Pleistocene (11 to 2 million years ago)

[1] David Hopley, Head of the Sir George Fisher Centre for Tropical Marine Studies at James Cook University, Townsville Australia. Peter J. Davies, Geologist, Bureau of Mineral Resources, Canberra, Australia.

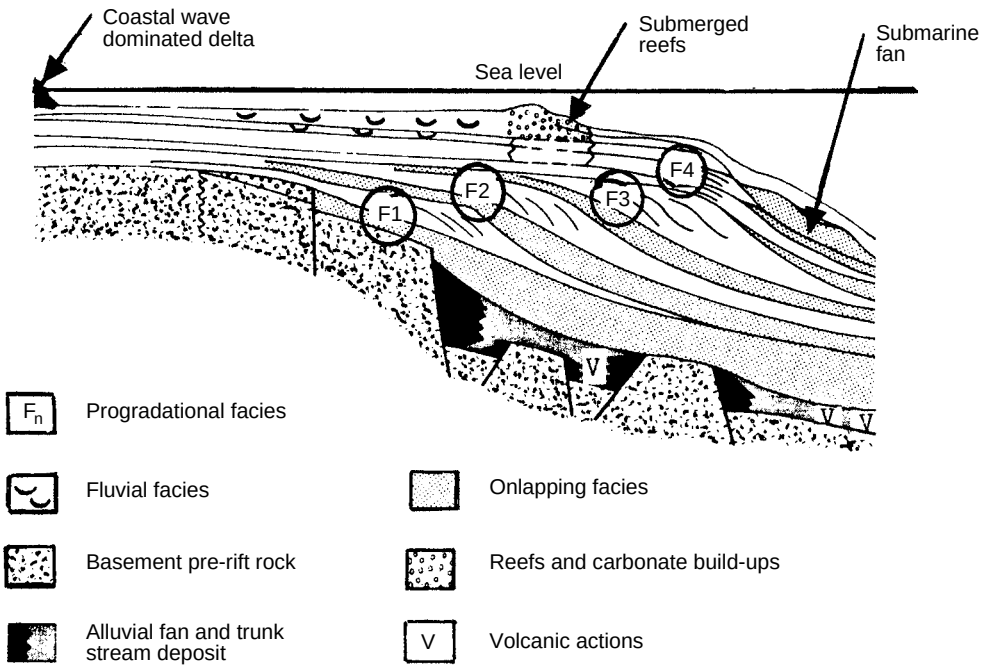

Fig. 2. Kinds of depositional system involved in the development of the shelf of the central Great Barrier Reef. (*After Symonds and Others.*)

produced about 10 km of shelf outbuilding off Cairns and about 50 km off Townsville, a sediment sequence about 2.4 km thick.

Seismic records, with exception of the northernmost reef region, show a distinctive lack of reef growth. Initially, this can be attributed to Australia's latitudinal position and seawater temperature too cool for coral growth, but subsequently high turbidity levels on the shelf during high sea-level periods may have produced conditions that were not conducive for reef building.

Earliest reef development was restricted to the Gulf of Papua shelf area, which would have reached the warm waters of the tropics earliest. By early and middle Miocene times (12 million years ago), barrier reefs had developed at the edge of a carbonate shelf and platform reefs had developed on highs in front of the shelf. However, following uplift and erosion, they were rapidly buried by massive Pliocene to Recent tide-dominated deltaic progradation.

To the south, the reef sequence is thin, less than 300 meters thick. It also is young, almost certainly less than 2 million years, i.e., mainly Pleistocene in age and built during a period of rapidly fluctuating worldwide sea levels. Reef growth has occurred during short periods of high sea level. During the intervening periods of low sea level, the reefs were subaerially eroded. Continual recolonization of sites throughout their growth history has produced reefs that are composite features made up of a series of remnant reefs separated by unconformities.

Hopley and Davies conclude their report with the observation that although the Great Barrier Reef is comparatively young geologically, it contains such a diverse range of environments that it may provide the model for development, maintenance, and management of continental shelf reef systems on a global scale. Until the late 1970s, the relatively small amount of information available on reef development came largely from locations outside the Great Barrier Reef province. Recognition that the reef is dynamic, not just during periods of rapid environmental fluctuations such as sea-level changes, but during, for example, the last 6500 years of relative sea-level and climatic stability, is important for a more complete understanding of ecology, and as the basis of management.

Coral Reef Research in the Caribbean

The Caribbean Coral Reef Ecosystems (CCRE) research group was formed in the early 1970s and now is made up of several sponsoring countries of the Caribbean region, including Barbados, Bermuda, Bahamas, Dominican Republic, Jamaica, Grenada, Mexico, the United States, and Venezuela, among others. Among the important targets of oceanographic and associated scientific research are coral reefs and mangrove swamp communities. The effects of petroleum contamination are also being studied.

Scientists in recent years have observed that the coloration of Caribbean coral reefs have been fading, a phenomenon called "bleaching." Former beautifully colored areas are being replaced by white blotches. As one scientist has described it, "Some are turning completely white, as if soaked with household bleach." It has been explained that the white color derives from a loss of the symbiotic, single-celled algae zooxanthellae, which normally lives within the tissues of marine animals. These microorganisms provide added nutrition, and the loss of this symbiont reduces the coral's ability to compete with other plants. It has been postulated that bleachings may result from unusually high temperatures, possibly caused by increased ultraviolet radiation due to ozone depletion. Or the condition may be caused by secondary pathogens after physical stress, as has been observed in prior fish mass mortalities.

CORAL TREE. Of the family *Leguminosae* (pea family), genus *Erythrina*, there are about 50 species of coral trees. A native tree of Brazil, the coral also is found in Africa (*E. caffra*), in India (*E. indica*), and quite commonly in the southeastern United States (*E. herbacea*), and in southern California. The height of the tree varies with climate, but some attain a height of 40 feet (12 meters) and a trunk diameter between 18 and 25 inches (46 and 64 centimeters). The leaf is trifoliolate and located at the end of the branch. Three or four large branches often grow out from the trunk up about 3 feet (0.9 meter) from the base of the tree. Smaller branches are numerous, smooth, and rather straight, gradually and slightly curving upward. These, in turn, produce a profusion of branches. The blossom is a bright red cluster of flowers located at the tip of the branch. However, some coral trees have yellow blossoms. There are from six to eight flowers in a cluster, with short stems. The flower varies from the size of a pea to 3 or 5 inches (7.5 or 12.5 centimeters) across. The tree may be described as quite spectacular when in bloom. The bark is smooth, with vertical patterning.

CORDIERITE. The mineral cordierite, composition $(Mg, Fe)_2Al_4Si_5O_{18}$ is an orthorhombic mineral frequently seen, however, in pseudohexagonal forms, as well as massive. It is brittle, with a subconchoidal fracture; hardness, 7–7.5; specific gravity, 2.53–2.78; luster, vitreous; color, blue of varying shades; translucent to transparent. Cordierite exhibits pleochroism (or dichroism) being dark blue, light blue and light yellow when examined by transmitted light in different directions. Hence, it is frequently called *dichroite*, and less frequently, *iolite*. It is occasionally used as a gem.

Cordierite is found as a primary mineral in the igneous rocks. It is, however, found ordinarily in gneisses, schists and in areas of contact metamorphism. Localities for good specimens are numerous in Europe, including Bavaria, Finland, Norway. It is found in Greenland, Madagascar and Sri Lanka, from which latter place come the rolled pebbles of a rich blue color known as saphir d'eau, prized as a gem. In the United States, it is found principally in Connecticut.

Named for the French geologist, Pierre Louis Antoine Cordier, this mineral has also been called iolite from the Greek word meaning violet, and stone, as well as dichroite from the Greek meaning *two-colored*.

CORE (Earth). See **Earth**.

CORE LOSS. In electrical machinery, magnetic cores provide easy paths for the flux which is necessary for the proper operation of the machines. The insertion of this core is not without its drawbacks, however, as it introduces additional losses known as core losses. In spite of the additional loss present in the magnetic material the overall effect of the core is a tremendous increase in the efficiency of the machine because of the smaller currents needed to produce the desired magnetic flux. The core losses are composed of *eddy current* loss and *hysteresis* loss. The former is caused by the currents that are induced in the core material by the changing flux through it. This is, of course, much more pronounced in A.C. than in D.C. machines because of the much greater rate of change of the flux in the former. In order to reduce this loss the core of all ac. machinery and much dc. machinery is laminated or composed of thin sheets. The hysteresis loss comes as a result of something like viscous friction opposing the reversal of magnetic field intensity. While the two types of losses do not follow the same laws, the total loss varies approximately as the square of the frequency if other factors are held constant, or about as the 1.5 power of the flux density if it is the only variable. See also **Hysteresis**.

CORE (Magnetic). Electromagnetic equipment, as exemplified by the transformer, the motor, and the generator, has electrical circuits, usually of copper conductors, and magnetic circuits. The magnetic circuit follows a path largely contained in a core composed of iron or iron alloys. The purpose of the core metal is to offer the best path for the magnetic lines of flux, and its success in this respect is measured by its permeability. Cores are usually composed of a large number of thin metal laminations, which are fabricated by punching from thin sheets of metal, and after being enameled are assembled to form a core. The enamel forms an insulation between laminations which reduces the eddy currents induced in the metal of the core by transformer action. Normal oxidation scale is frequently sufficient insulation for this.

CORE SAMPLER (Piston corer; Kullenberg corer). A long slender tube with an internal piston. The tube is lowered slowly to the ocean floor where it is suddenly released while the piston remains in place. The tube bores into the ocean floor and a core of the sea floor is drawn into the tube as a consequence of the partial vacuum created by the piston. A major tool used in oceanography.

COREY, ELIAS JAMES (1928–). An American who won the Nobel Prize for chemistry in 1990 for development of novel methods for the synthesis of complex natural compounds (retrosynthetic analysis). He specialized in synthesis of terpines. He was awarded is doctorate by M.I.T. in 1951.

CORIANDER SEED. See **Spices**.

CORI, CARL FERDINAND (1896–1984). Carl F. Cori was a Czech-born (then Austria-Hungary) American biochemist who carried out pioneering work on carbohydrate metabolism.

Cori was born in Prague (then part of the Austro-Hungarian Empire), but grew up in Trieste, Italy. In 1914 he returned to Prague to begin medical studies at the German University; he met Gerty Radnitz during his first term, and they married in 1920. In 1922 Cori obtained a position as a biochemist at the New York State Institute for the Study of Malignant Diseases; his wife joined him there, and they became American citizens in 1928. After moving to Washington University in St Louis, Cori held successive professorships of pharmacology and biochemistry (1931–1966). He then served as visiting professor at Harvard Medical School until his death. See also **Cori, Gerty Theresa Radnitz 1896–1957**.

Cori worked so closely with his wife on problems of carbohydrate metabolism that it is nearly impossible to separate his contributions from hers. During the 1930s they began to investigate the steps involved in the conversion of glycogen to glucose, and discovered the mechanism that governs the process (the Cori cycle). They showed the involvement of sugar phosphates (*Journal of Biological Chemistry*, 1939) and the key role played by phosphorylase. For this research the Cori's became the third married couple to win a Nobel Prize: they were awarded (with Bernardo Houssay) the 1947 prize in Physiology or Medicine.

CORI, GERTY THERESA RADNITZ (1896–1957). Gerty Radnitz Cori was a Czech-born (then Austria-Hungary) American biochemist who carried out pioneering work on carbohydrate metabolism.

Gerty Radnitz was born in Prague, which was then part of Austria-Hungary. As medicine was then the best entry into biological science, in 1914 she became a medical student at the German University of Prague; she married her classmate Carl Cori after their graduation in 1920. Two years later they immigrated to Buffalo, New York, where both worked at the State Institute for the Study of Malignant Diseases. In 1931 they went to Washington University in St Louis, where she held successive appointments as a research associate in pharmacology and, from 1947, Professor of Biochemistry. See also **Cori, Carl Ferdinand (1896–1984)**.

Throughout her career Cori worked closely with her husband, primarily on aspects of carbohydrate metabolism. They discovered the mechanism by which glycogen is converted into glucose in the body, and isolated phosphorylase, an enzyme that is integral to the process (*Journal of Biological Chemistry*, 1943). This was the first time that carbohydrate metabolism was studied at a molecular level. Later work identified other

enzymes involved in glycogen metabolism. In 1947 the Cori's were awarded (with Bernardo Houssay) the Nobel Prize in Physiology or Medicine, Cori being the third woman to win a Nobel Prize in science. In the same year she developed myelosclerosis, which eventually proved fatal. See also **Biochemistry (The History)**.

CORING. A fine scale or microscopic variation in composition within the grains of a metal casting. Coring is usually associated with a solid solution phase and is caused by failure to achieve equilibrium during freezing. The alloy initially solidifies in the form of dendrites or skeleton crystals that contain a greater proportion of the higher melting components. The spaces between the dendrite arms freeze later with a composition lower in the higher melting components.

CORIOLIS ACCELERATION. An acceleration of a parcel moving in a relative coordinate system.

The total acceleration of the parcel, as measured in an inertial coordinate system, may be expressed as the sum of the acceleration within the relative system, the acceleration of the relative system itself, and the Coriolis acceleration. In the case of the earth moving with angular velocity Ω, a parcel moving relative to the earth with velocity $\mathbf{u}$ has the Coriolis acceleration $2\Omega \times \mathbf{u}$. If Newton's laws are to be applied in the relative system, the Coriolis acceleration and the acceleration of the relative system must be treated as forces.

See also **Apparent Force**; **Coriolis Force**; **Gravitation**; and **Inertial Force**.

CORIOLIS EFFECT. Any object moving above the earth with constant space velocity is deflected relative to the surface of the rotating earth. This deflection was first discussed by the French scientist Coriolis about the middle of the nineteenth century, and is now usually described in terms of the Coriolis acceleration or the Coriolis force. The deflection is found to be to the right in the Northern Hemisphere and to the left in the Southern.

As a first approximation to the problem we assume that an observer is at the center (C) (see Fig. 1) of a disk that is rotating with constant angular velocity ω. In part (a) of the figure, the observer can see objects off the disk and is conscious of the rotation. At a given instant, when the object P on the disk is directly in line with the point P' off the disk, the observer fires a shot at P. During the time (t) that is required for the shot to move over the distance CP at speed v ($CP = vt$), the disk will turn through the angle θ ($\theta = \omega t$). The observer notices that the bullet misses the point P, but that it hits In Fig. 1(b) the observer's "world" is limited to the rotating disk and he has no way of knowing that his world is in rotation. Under these conditions when he fires a shot at P he will notice, as before, that the bullet misses P, and he will also determine that the shot follows a curve, similar to that shown, in his world. The same effects will be observed no matter where the observer is located in his world or what direction he aims his shot (e.g., from A in direction BB' or from B toward AA'). The deflection is always to the right with the direction of rotation indicated in the figure, and would be to the left if the direction of rotation were reversed.

In accordance with fundamental definitions a curved motion represents an acceleration (a) and an acceleration is the result of the action of a force (f) which is proportional to the mass (m) of the object and the speed (v) with which it is moving. Analysis of the motions shown in the figure show that the acceleration relative to the disk is given by $a = 2v\omega$ or, since $\omega = (2\pi/T)$, in which T is the period of rotation, $a = (4\pi/T)v$. The force producing this acceleration will be given by $f = k(4\pi/T)mv$,

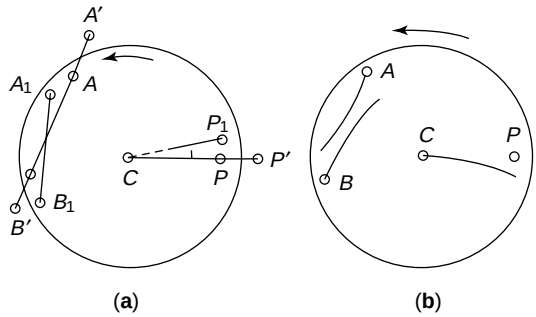

Fig. 1. Coriolis effects.

in which k is a factor of proportionality whose value is determined by the units employed.

The conditions on the rotating earth in the vicinity of either pole of rotation are comparable to the "world conditions" on the rotating disk. The sense of rotation will be opposite at the two poles and the deflection will be to the right at the north pole and to the left at the south. The angular velocity of rotation of an area at any place on the earth in latitude L is given by $\omega = (2\pi/T)$ sin L, in which T is the sidereal period of rotation of the earth or 86,163.4 seconds. Hence the Coriolis acceleration is $a_c = (4\pi/T)v$ sin L, and the Coriolis force $F_c = k(4\pi/T)mv$ sin L.

The Coriolis effects must be considered in a great variety of phenomena in which motion over the surface of the earth is involved. Among these may be listed the following: (1) Rivers in the Northern Hemisphere should scour their right banks more severely than the left, and the effect should be more evident for rivers in high latitudes. Studies of the banks of the Mississippi and Yukon rivers indicate the predicted results. (2) The motions of air over the earth are governed, to an appreciable extent, by the Coriolis force. (See also **Winds and Air Movement**.) (3) A term, due to the Coriolis force, must be included in the equations for exterior ballistics. While the effect is negligible in small-arms fire, nevertheless, it is very important in the fire-control material for long-range guns. (4) Any level bubble, which is being carried on a ship or plane, will be deflected from its normal position. The deflection will be perpendicular to the direction of motion of the ship or plane. The correction for this effect may amount to several miles in the determination of a position of the ship or plane by methods of celestial navigation if the bubble octant is used in the necessary observations. See also **Sextant**.

CORIOLIS FORCE. An apparent force on moving particles in a noninertial coordinate system, that is, the Coriolis acceleration as seen in this (relative) system. Also called *compound centrifugal force* and *deflecting force*.

Such a force is required if Newton's laws are to be applied in this system. In meteorology the Coriolis force per unit mass arises solely from the earth's rotation, and is equal to $-2\Omega \times \mathbf{u}$, where Ω is the angular velocity of the earth and $\mathbf{u}$ is the (relative) velocity of the particle. Thus the Coriolis force acts as a deflecting force, normal to the velocity, to the right of the motion in the Northern Hemisphere and to the left in the Southern Hemisphere. It cannot alter the speed of the particle. The three components toward east, north, and zenith are, respectively, 2Ω ($v \sin\varphi - w \cos\varphi$), $-2\Omega u \sin\varphi$, and $2\Omega u \cos\varphi$, where u, v, w are the component velocities and φ the latitude. Since the Coriolis force is in effect proportional to the speed, its importance in any given atmospheric motion may be judged from the representative speed and duration of the motion. See also **Coriolis Acceleration**; and **Zenith**.

AMS

CORIOLIS, GASPARD GUSTAVE DE (1792–1843). Coriolis was a French mathematician and Physicist. He studied at the Ecole Polytechnique and later taught there. In 1829, he became the chair of mechanics at the

Ecole Centrale des Arts et Manufactures. Later he worked in applied mechanics, sometimes with Claude-Louis-Marie-Henri Navier, at Ecole des Ponts et Chaussees.

Coriolis is especially remembered for his achievement in discovering and analyzing forces in a rotating system, and also, his Coriolis force that influenced mechanical physics.

See also **Coriolis Effect**.

J. M. I.

CORIOLIS PARAMETER. Twice the component of the earth's angular velocity about the local vertical, $2\Omega \sin\varphi$, where Ω is the angular speed of the earth and φ is the latitude.

Since the earth is in rigid rotation, the Coriolis parameter is equal to the component of the earth's vorticity about the local vertical. If the Coriolis parameter is denoted by f and the speed of a horizontally moving fluid parcel by V, then fV is the magnitude of the horizontal Coriolis force per unit mass on the parcel. See also **Coriolis Force**; and **Rossby Parameter**.

CORK. Cork cells are found in the outer bark of most woody-stemmed plants, but in amounts too small and with too brittle walls to be of any use to man. But in *Quercus suber*, the Cork Oak, the cork cells become a very large part of the tissue of the bark, and have been used for centuries by man. The cork oak tree is a medium-sized tree, seldom much over 50 feet (15 meters) in height, growing in nearly all countries bordering the Mediterranean Sea. The evergreen leaves are small, $1\frac{1}{2}-3$ inches long, and about an inch wide, with slightly toothed margins. The bark of the tree soon becomes rough and deeply furrowed, but is of little value except as ground cork or as a source of tannin. When the tree is about 20 years old this first formed bark is removed, care being taken not to injure the phloem and cambium layers. Within 10 days a new cork layer has formed. This layer is the first of many layers which are removed once every 10 years or so throughout the life of the tree. Removal is generally done in the early summer at a time when hot dry winds will not cause injury to the unprotected phloem and cambium.

After removal, the cork is air-dried for a time, then boiled to soften it and to remove some of the tannin. The outer part of the bark is scraped off, and the rest pressed out flat and dried. It is then ready to ship.

The physical properties of cork account for its many uses. It is very light and buoyant, more than 50% of its volume being air, and hence is used in the manufacture of floats, life-preservers, and so forth. The living protoplasm of the cork cells dries up early in their development, leaving hollow cells, each containing a small mass of air which expands after compression. Therefore, cork is very resilient, and is frequently used as a core on which to wind yarn or string in the manufacture of baseballs. In the early stages of their formation, the walls of cork cells are cellulose, but this is soon impregnated by a waterproof and nonabsorbent lipoid substance, suberin. Therefore cork is used in making handles for fishing rods, shoe-soles, and cork stoppers. Since the hollow cork cells are poor conductors both of heat and sound, cork is much used as insulating material. For this use cork is ground up and then pressed into sheets with various binding materials, giving much larger sheets than can be obtained from the tree. Ground cork is also a constituent of linoleum, gaskets, and other products.

Cork is traversed by lenticels, loose masses of porous tissue, which appear as dark spots or holes in stoppers. Usually in making stoppers the bark is cut so that these will be transverse in the stopper. In making stoppers, the forms are first punched out as cylinders, and then trimmed down by machine to the required tapering shape.

CORKWOOD TREE. Of the family *Leitneriaceae*, the corkwood (*Leitneria floridana*) is a small deciduous tree, seldom exceeding a height of 20 to 25 feet (6 to 7.5 meters) and with a narrow trunk of about 6 inches in diameter. The tree is found in the southeastern United States and also in the regions of Arkansas and Texas. The bright green leaf is about 5 inches (12.5 centimeters) long, 2 to 3 inches (5 to 7.5 centimeters) across, and quite hairy on the underside. The fruit is of oval shape, leathery, unveined, flat, and brown in color. The wood of this tree is among the lightest, weighing about 13 pounds per cubic foot (208 kilograms per cubic meter). It finds limited application in fishing tackle. This tree is not to be confused with the balsa tree, the wood of which is even lighter. The balsa is sometimes also referred to as corkwood or Indian corkwood. See also **Balsa Tree**.

CORM. 1. In botany, a corm is a very short, thick, subterranean stem distinguished from the rhizome by erect instead of horizontal growth. Its surface shows more or less distinct nodes. From the nodes of the upper portion, buds develop. Generally, roots are formed in the lower part of the corm. In many plants the corm is surrounded by scaly leaves or leaf bases. The crocus and the gladiolus produce corms.

2. In zoology, the corm is the median branch or endopodite of the appendage of certain crustacea together with the common basal portion. When the expodite is reduced, these parts sometimes appear as the principal axis of the appendage.

CORMACK, ALLAN MACLEOD (1924–1998). Allan Cormack was a South African/American physicist who jointly invented the medical diagnostic technique known as computer-assisted tomography (CAT).

Born in Johannesburg of Scottish parents who had emigrated to South Africa, Allan Cormack was educated at Rondebosch Boys High School, Cape Town. Having first considered a career as an astronomer he decided instead to become an electrical engineer. However, during his studies at the University of Cape Town (UCT) he found physics and mathematics more attractive than engineering and graduated with a BSc in physics in 1944, followed by an MSc in X-ray crystallography in 1945.

After a period as a junior lecturer in physics at UCT Cormack moved to the Cavendish Laboratory, Cambridge, where he worked on radioactive helium (^{6}He) under Professor O. R. Frisch. In 1950 he returned to South Africa to again take up a lectureship in physics at UCT where he remained until 1956, gaining a reputation as an inspiring lecturer.

In 1955, following the resignation of the medical physicist at Groote Schuur Hospital, an institution closely allied with UCT (and where Professor Christiaan Barnard was later to perform the world's first heart-transplant operation), Cormack was requested to spend one and a half days a week there. In planning the radiotherapy treatment of cancer patients there, Cormack became increasingly aware of the problem of the attenuation of radiation as it passed through the human body. In his own words, "I asked myself how can you give a dose of radiation if you don't know the material through which it has to pass?" Working in his spare time during the period of sabbatical leave at Harvard that followed, Cormack developed a mathematical theory of the absorption problem. Although he had meanwhile accepted a post at Tufts University in Massachusetts, he returned to UCT for the third quarter of 1957 and during this time tested his theory by performing a seminal experiment in which he measured the absorption of the radiation from a 7-mCi ^{60}Co source by an aluminium and wood "phantom" body constructed in the Physics Department workshops. His measurements agreed remarkably well with theory.

At Tufts Cormack continued working on the problem in his spare time, improving his mathematical theory and also performing another experiment, but this time using a non-symmetrical phantom of plastic and aluminium. Once again theory and practice agreed and he accordingly published his results in two papers in the *Journal of Applied Physics*. However, neither appeared to evoke any significant response–as was indeed also the case when he showed his results to a number of medical physicists–in spite of the fact that his work showed that three-dimensional images of the interior of the human body, the production of which up to this time had been impossible, were in fact feasible.

Meanwhile, some years later G. N. Hounsfield, working at EMI Ltd in Hayes, England, had quite independently come to conclusions similar to Cormack's but had concentrated instead on developing the equipment necessary to put these ideas into practice. In 1971 the first clinical machine designed for head scanning was installed in a hospital in Wimbledon, London. This technique, which has come to be known as computer-assisted tomography (CAT), is now used widely throughout the world and is universally accepted as a diagnostic technique of quite extraordinary, indeed unmatched, power. See also **Computed Tomography**.

In 1979 Cormack and Hounsfield were jointly awarded the Nobel Prize in Physiology or Medicine, the award being especially noteworthy in that neither of the prizewinners had any formal training in either physiology or medicine! They met for the first time at the award ceremony in Stockholm. See also **Hounsfield, Godfrey Newbold (1919–2004)**.

In 1950 Cormack married Barbara Seavey, daughter of the Dean of the Harvard Law School. He became an American citizen in 1966, remaining at Tufts until his retirement in 1980.

CORMIDIUM. A group of individuals of various forms budded from the parent stalk of certain floating marine coelenterates.

CORNEA. The tough, clear membrane that covers the front of the eye and protects the inner parts of the eye is called the cornea. It serves as the outer lens of the eye and provides approximately 70 to 80% of the eye's refractive power. Fine-tuning is provided by the natural crystalline lens that lies behind the pupil. Together these two lenses focus light on the retina at the back of the eye, which sends electrical signals to the brain enabling a person to see. The shape of the cornea and its general condition determine, to a large degree, the visual powers of the eye. The cornea comprises five layers. The outermost layer is called the *epithelium*. It is a covering like the skin, only it is transparent. The majority of nerve endings of the cornea are in this layer, which is why the cornea is sensitive to touch. If damaged, the epithelium grows back in a few days without scarring. Tear film lubricates the epithelium, and inadequate tear film results in dry eye.

Just below the epithelium is the *Bowman's membrane*. Composed of strong collagen fibers, this smooth layer helps the cornea maintain its shape. If the Bowman's membrane is damaged, scarring will normally occur.

The third and thickest layer of the cornea is the *stroma*, a layer of neatly compacted fibers that provide the strength for the eye to withstand trauma. Regular spacing of these fibers is critical to the clarity of the cornea. Infection, injury, or disease to the stroma will heal. However, scar tissue may cause a disruption in the collagen pattern, resulting in decreased vision.

Decemets' membrane is located directly behind the stroma. It serves as a barrier to infectious organisms while allowing water and nutrients to pass through.

The fifth and innermost layer of the cornea is the *endothelium*, which is a delicate, one-celled-thick layer that acts as a fluid regulator for the stroma. It maintains the cornea in a relative state of dehydration, thereby keeping the collagen fibers neatly compacted and allowing the transmission of light.

Although the cornea contains the highest concentration of nerve fibers of any structure in the human body, it contains no blood vessels. That is one reason why the cornea remains clear. The cornea receives nutrition from the fluid interior of the eye and from the outer tear film surface. See also **Dry Eye**; **Keratoconus**; and **Vision and the Eye**.

Vision Rx, Inc., Elmsford, NY

CORNEAGEN CELL. A kind of cell found in the eyes of some insects. It produces the transparent lenticular cornea at the outer surface of the eye and is renewed on ecdysis.

CORNEAL ABRASION. A corneal abrasion is a scraped, scratched, or torn area of the corneal surface (named the epithelium), usually resulting from an injury such as a finger in the eye, a tree branch, flying glass, or damage from a contact lens. In some corneal abrasions, the Bowman's membrane, which is a layer just below the epithelium, may also be damaged. The cornea contains more nerve endings than virtually any other part of the body. Therefore, damage to the cornea is extremely painful. Corneal abrasion is one of the most common injuries to the eye.

The most common symptoms of a corneal abrasion are redness, pain, blurred vision, excessive tears, sensitivity to light, or a feeling that an object is in the eye. Most such abrasions occur in one eye only, and many result from wearing contact lenses improperly.

In many cases, depending on the severity, the cornea will heal completely in 24 to 48 hours, leaving no permanent damage. However, if the pain is severe or persistent, contact an eye doctor to decide if treatment is required. An anesthetic eye drop is used during the examination to ease the pain, and the most common treatment is antibiotic drops or ointment to prevent infection.

The eye is normally covered with a tight patch after treatment to prevent the eyelid from moving. This patch is usually worn for at least 24 hours to prevent the healing cells from being disturbed and causing continuing problems. New cells require time to reconnect to the undamaged layers of the cornea. Contact lens wearers should not wear lenses for at least 24 hours following treatment, because the contacts could slow the healing process. Medications may also stain or cloud soft lenses. Superficial abrasions rarely cause permanent loss of vision. However, it may take several weeks for clear vision to return, and it is imperative during the healing process not to rub your eyes.

Sometimes, long after an abrasion has healed, it can recur spontaneously. This recurrence can appear when you wake up in the morning. It happens when an area of the epithelium has not reconnected to the deeper parts of the cornea. Treatment is similar to that for the original abrasion. The eye care professional can use a special instrument to help form better connections between corneal layers. Ointments and/or lubricants may also help in preventing recurrent erosions.

Corneal abrasions can often be prevented with a few precautions. Exercise extreme care when using any objects near the eyes. Wear protective goggles when working around any materials that may fly up near the eyes. Trim low-hanging tree branches in the yard. Wear goggles or glasses when walking through areas of heavy brush. If you wear contact lenses, be careful putting them in and taking them out. Keep the fingernails of infants and small children clipped short. See also **Cornea**.

CORNEAL DYSTROPHY. Corneal dystrophy is the gradual deterioration of one layer or another of the cornea, the transparent outer layer of the eye through which light enters. The cornea comprises five layers of tissue. Starting from the outside, the layers are the surface epithelium, its basement membrane, the stroma (the thickest layer, constituting 90% of the cornea), the internal endothelium, and its basement membrane. The endothelium acts to remove excess moisture, thus preventing abnormal swelling of the cornea.

There are a variety of corneal dystrophies. They can affect the epithelium, the troma, or the endothelium. They often are inherited and can occur at an early age, even at birth. The two most common are epithelial basement membrane dystrophy and endothelial cell dystrophy.

Epithelial basement membrane dystrophy generally occurs in adults after the age of 40, and it can come as late as age 70. In this form of dystrophy, the basement membrane begins to become thick and irregular, so that the once-even layer of cells starts to buckle as the cells break apart and fall off the membrane. A magnified view of an affected membrane under a slit lamp will show an irregular pattern of cysts, ridges, and whirls. Ophthalmologists call the condition "map-dot-fingerprint dystrophy."

The breakdown of the basement membrane in epithelial cell dystrophy causes redness of the eye and discomfort that can range from moderate irritation to severe pain. Those symptoms generally are worse at the start of the day, because sleep does not permit the blinking that keeps the surface of the cornea lubricated with tears.

Treatment for corneal epithelial cell dystrophy usually starts with efforts to augment the natural lubrication, using artificial tears and saline solutions just before sleep and eye drops applied periodically during the day. The patient may be told to wear a customized eye patch or contact lens to achieve the necessary lubrication. Also, measures to keep the home environment more humid, using vaporizers or similar equipment, may be recommended. If these measures fail, surgery or laser therapy to remove unlubricated cells may be needed.

Corneal endothelial cell dystrophy, also called Fuch's dystrophy, also is most common in adults in their 40s and 50s, affecting women more than men. It, too, tends to be hereditary, and it generally affects both eyes. Fuch's dystrophy occurs when the natural pumping activity of the endothelium begins to deteriorate. Excess fluid starts to accumulate, causing the cornea to become swollen and less transparent, so that visual ability can deteriorate with time.

The most noticeable symptom of corneal endothelial cell dystrophy is blurry vision, particularly evident at wake-up time because while the eyes are closed during the sleep, less fluid is able to evaporate. Vision improves as the day goes on, as more fluid evaporates. To treat for endothelial cell dystrophy, steps are taken to remove moisture from the eyes, using

different ointments and eye drops. But these measures often fail to stop the progression of the condition, so a corneal transplant may be needed, using tissue taken from the eyes of a donor. Tissue matching to prevent rejection of the transplanted tissue is not as important for a corneal transplant as for other organs. Because the cornea has very few blood vessels, it is less exposed to attack by the immune system. Corneal transplants were, thus, the first to be widely successful in human patients. A network of eye banks exists to obtain corneal tissue and match it for appropriate patients.

Cataract operations and other kinds of eye surgery can increase the risk and hasten the progression of endothelial cell dystrophy by causing edema, a buildup of fluid. Persons with a family history of this kind of corneal dystrophy are advised to tell their doctors when any such surgery is planned. They are also advised to undergo regular examinations to detect the condition at its earliest, most treatable stage. See also **Cornea**.

CORNEAL TOPOGRAPHY (Videokeratography). Also known as videokeratography, corneal topography is a process for mapping the surface curvature of the cornea, similar to making a contour map of land. The cornea is a clear membrane that covers the front of the eye and is responsible for about 70% of the eye's focusing power. To a large extent, the shape of the cornea determines the visual ability of an otherwise healthy eye. A perfect eye has an evenly rounded cornea, but if the cornea is too flat, too steep, or unevenly curved, less than perfect vision results.

The purpose of corneal topography is to produce a detailed description of the shape and power of the cornea. Using computerized imaging technology, the 3-dimensional map produced by the corneal topographer aids an ophthalmologist in the diagnosis, monitoring, and treatment of various visual conditions.

The corneal topographer is made up of a computer linked to a lighted bowl that contains a pattern of concentric rings. The patient is seated in front of the bowl with his or her head pressed against a bar while a series of data points are generated on a placido disk, that has been projected on the cornea. Computer software digitizes these data points to produce a printout of the corneal shape, using different colors to identify different elevations.

The procedure itself is painless and brief. It is a noncontact examination that photographs the surface of the eye using ordinary light. The greatest advantage of corneal topography is its ability to detect conditions invisible to most conventional testing.

Corneal topography is not a routine test. Rather, it is used in diagnosing certain types of problems, in evaluating a disease's progression, in fitting some types of contact lenses, and in planning surgery. It is commonly used in preparing for refractive eye surgery. The corneal topography map is used in conjunction with other tests to determine exactly how much corneal tissue will be removed to correct the visual defect.

Corneal topography is used in the diagnosis and management of various corneal curvature abnormalities and diseases such as: keratoconus, a degenerative condition that causes a thinning of the cornea; corneal transplants; corneal scars or opacities; corneal deformities; fitting contact lenses; irregular astigmatism following corneal transplantation; planning refractive surgery; and postoperative cataract extraction with acquired astigmatism.

Prior to the advent of corneal topography, several tests and a great deal of time were required to photograph, calculate, and then translate data into some meaningful description of the corneal shape. The personal computer automates the process. See also **Keratoconus**; and **Refractive Eye Surgery**.

CORN EARWORM *(Insecta, Lepidoptera).* Many millions of acres of corn (maize) have been attacked and destroyed by this insect over the years in the United States and other regions of the world. In the United States, the pest is most damaging in the southern states. Although its damage is usually associated with corn, the insect is a general feeder and will attack numerous crops, such as bean, cotton, lettuce, tobacco, okra, tomato, and vetch. When found on tobacco, it may be called the tobacco budworm; or if found on tomato, the tomato fruitworm; or if on cotton, the cotton bollworm. The adult corn earworm is a moth of the family *Notodontidae*. The official species name is *Heliothis zea* or *H. armigera*, Boddie. In some regions, records indicate that nearly 100% crop loss has resulted from heavy infestations of this pest.

The insect winters over as a brownish pupa, usually found several inches in the soil below groundlevel. Moths emerge in spring and early summer. The moth is relatively large, with a wingspread of about 1.5 inches (nearly 4 centimeters). The moths are of a rather nondescript coloration, ranging from gray to brown to olive green. Markings are irregular. After emerging, the moth consumes nectar from nearby flowers. The female deposits yellow eggs in the evening, singly, even though the total number may be as high as 3000. Depending upon latitude and prevailing seasonal temperatures, there may be as many as 3 generations of the insect per year. The eggs early in the season are placed among the curl of early-leafing plants. For subsequent generations, corn silk is one of the preferred locations. Hatching requires up to 10 days. The emerging worms feed on the corn silk. When the silk has lost much of its moisture, the worms move on to the kernels of the ear and feed on the ear for 2 to 4 weeks, during which time they molt 5 times. When fully grown the worms are striped, green-brown in color, and about 2 inches (5 centimeters) long. Their damage is extended because a single worm may move over more than one ear. When fully grown, the worms (larvae) drop to ground level, where they excavate a cell in the soil, up to 5 inches (about 12 centimeters) deep. They pupate in this location for 1.5 to 2.5 weeks, after which they emerge as moths.

Corn that is to be used for fodder adds to the difficulties of chemical controls. Fall mowing reduces the population of overwintering pupae. Within recent years, corn earworm-resistant varieties have become available and greatly reduce the damage from this insect.

CORNER REFLECTOR (Optics). A reflector that consists of two plane-conducting surfaces set at an angle of 45° to 90° with the driven element on a line bisecting the angle. The reflecting surfaces are not necessarily solid, but can be made from wires spaced about 0.1 wavelength apart. In a given amount of space, the corner reflector gives better directivity than the parabolic reflector.

CORNFORTH, JOHN (1917–). An Australian-born chemist who won the Nobel Prize for chemistry in 1975 with Vladimir Prelog for work on the chemical synthesis of organic compounds. Although deaf since childhood, he attained his doctorate from Oxford and held prestigious posts all over the world, as well as authoring many papers on organic and biochemical subjects.

CORN *(Maize).* In the United States, the word corn signifies Indian corn or maize, *Zea mays*. In Europe, the word is used for several cereal grains; in England for wheat; in Scotland and Ireland for oats. In its original use, corn designated a hard seed or grain.

There has been considerable speculation as to the origin of this plant. Everything indicates that it is native to America, probably originating in Mexico or Central America. The plant is not known to occur in the wild state, but a native Mexican grass, teosinte, Euchlaena mexicana, is a closely related grass with which corn hybridizes freely. Some botanists hold that teosinte is the ancestral grass from which corn originated. See Fig. 1.

There are many kinds of corn in cultivation, ranging from dwarf forms less than 3 feet (0.9 meter) high to giant plants 15 feet (4.6 meters) or more in height. All kinds have an extensive fibrous root system, the individual roots not only occupying the surface portion of the soil but also extending downward to depths of 6 feet (1.8 meters) or more. In addition to these normal roots, which all arise from the basal portions of the very young stem, prop roots develop from the lower nodes of the older stem. These prop roots are coarse outgrowths that radiate outward and downward until they reach the surface of the ground. During their growth in the air, their tips are protected from drying by an abundant slime coating; once they have entered the ground they branch abundantly and become like normal roots. They serve to support the plant. The stem of the corn plant is coarse and, unlike other grasses, solid throughout its length. The leaves, borne alternately on the stem, have large broad blades at the base of which is a conspicuous ligule, a membranous outgrowth which tightly invests the stem and so may serve to prevent water entering between the stem and the leafsheath.

The corn plant (Fig. 2) is monoecious, that is, both staminate (stamen) and pistillate (pistil) flowers are borne on the same plane. However, they are usually not borne in the same inflorescence. The staminate inflorescence

Fig. 1. Probable precursor of the corn (maize) plant known as teosinte (*Euchlaena mexicana*): (1) plant; (2) branch with staminate and pistillate inflorescences; (3) ear; (4) grains with attached stigmas; (5, 6) mature grains. (*USDA diagram*).

Fig. 2. Corn (maize) plant (*Zea mays*.) (*USDA photo*).

or tassel appears at the top of the plant, and matures some time before the pistillate flowers do. The male flowers produce immense quantities of pollen which when ripe is shed in the air, to be carried by wind currents or gravity to the pistillate flowers. Corn pollen is a cause of hay fever. See also **Allergy**. The pistillate inflorescence, or ear, is a modified branch developing in the axis of a leaf. This branch has a fleshy axis or cob on which are borne rows of pistillate flowers. These occur in two flowered spikelets, the lower flower usually being abortive, but its bracts, the lemma and palea persisting, as do the two short glumes, which subtend the entire spikelet. The ovary bears a long style, commonly known as the silk of the corn. When first developed the silk is green and has a sticky surface; after pollination has occurred, the silk turns brown and dries up. The entire pistillate inflorescence is enclosed in many overlapping modified leaves known as husks, from the tip of which the silk protrudes.

The mature corn grain is variously shaped according to the kind of corn. In most species it is a flattened object with a shallow groove on one side, indicating the location of the embryo. This embryo is on one side of the grain, the rest of which is filled with a starchy substance, the endosperm. This endosperm is usually separable into two parts, one hard and horny, called the horny endosperm; the other less firm and of lighter corn, known as the starchy endosperm. The horny portion contains more protein than does the starchy and has its starch grains more densely packed together.

The corn grain will not germinate unless the temperature is about 40 °F (4.5 °C) and sprouts best when the temperature is about 90 °F (32 °C). It is grown most successfully in regions having a deep, warm, well-drained loam soil, an abundance of rainfall and a growing season of 90 days or more, depending on the kind of corn. Improved varieties have been developed which grow satisfactorily in regions having a shorter growing season. Corn is principally grown in the Americas, especially in the United States and Argentina. It has been introduced in European countries and into Africa, but is not grown there to any great extent. In the United States the so-called Corn Belt grows more than half the entire world crop. This Corn Belt comprises the states from Ohio west to South Dakota and south to Kansas, a region having climatic conditions most favorable for this crop. Almost all of the corn produced today is hybrid corn. See also **Green Revolution**.

The uses of the corn crop are many and varied. The green plants are fed to stock directly or are stored in silos. For storage in silos the entire plant is cut down and chopped into small pieces. These are compactly stored in large tight structures of wood, concrete or other material, in which partial fermentation occurs, forming a product called ensilage. This is an important part of the ration of dairy cows.

Corn grains form a most important food product for humans and domesticated animals. The ripe ears are picked from the plants and allowed to dry. The grain is then removed from the cob and used directly as stock and poultry food or ground into coarse particles known as cracked corn, much used in feeding poultry. Ground somewhat finer, but still consisting of coarse particles, white corn becomes grits, much used in southern states. More finely ground, corn becomes corn meal, used in making corn bread and various kinds of puddings. Rarely corn is finely ground to flour. Another corn preparation is hulled corn. In making hulled corn, the grain is soaked in lye, which loosens the pericarp or outer portion of the grain. This is then removed and the remaining grain cooked soft. As a breakfast food corn appears principally in the form of corn flakes. In making these, clean corn grains are steamed and the hulls and embryo removed, leaving the endosperm. This is sweetened and flavored, and then cooked by steam under pressure. Following this cooking, the grains are partially dried and then passed between heavy rollers, which make them flakes. These flakes are carried to huge ovens where they are quickly toasted. Cooling follows, after which the product is packed in waterproof cases and is ready for the consumer.

In addition to use as food for man and beast, corn yields many important secondary products, such as corn starch, glucose (see also **Carbohydrates**) and corn oil. Starch is prepared from corn by soaking the grains in slightly acidulated water for several days, after which they are broken up, the embryos removed and the grain ground. Following the grinding, the whole is passed through sieves, which remove the pericarp. The resulting paste is allowed to flow slowly over tilted tables, which allows the starch to settle. This starch is washed and dried, then pulverized for use. See also **Starch**.

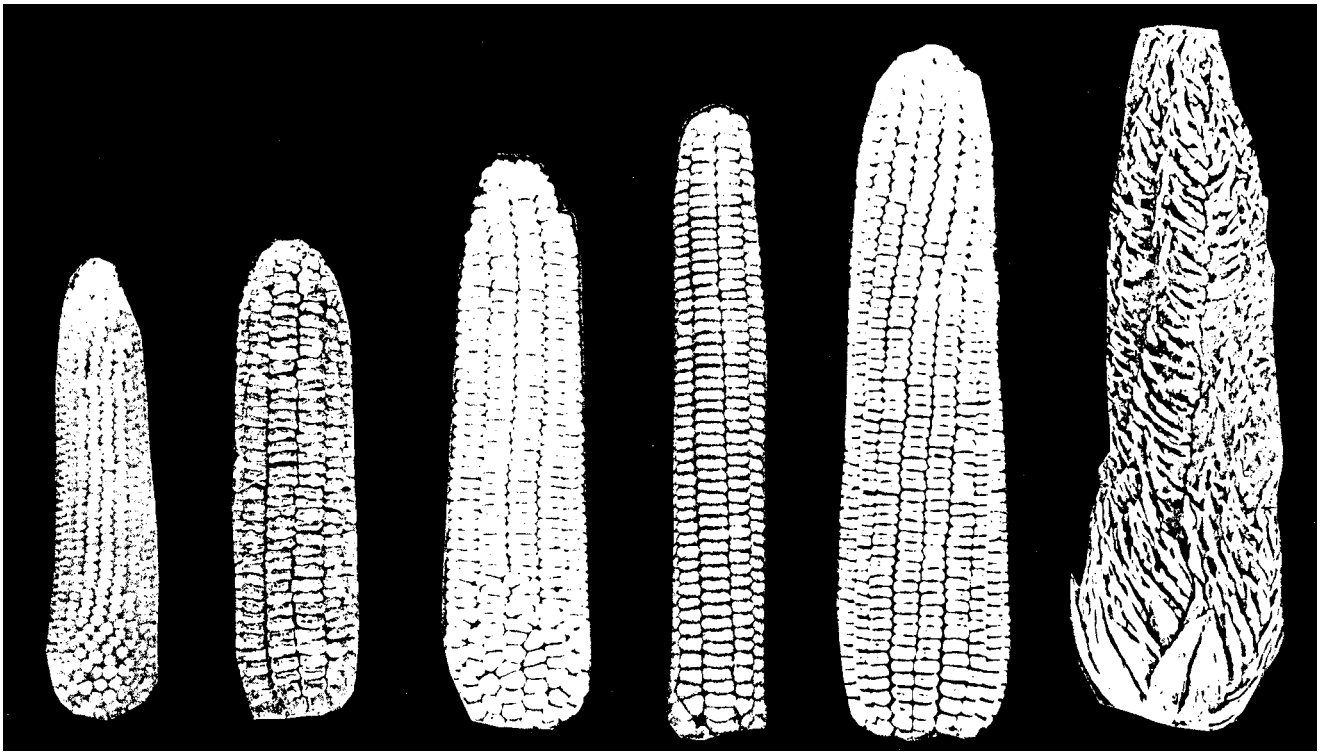

Fig. 3. Ears of six types of corn (maize). From left to right: Popcorn, sweetcorn, flour corn, flint corn, dent corn, and pod corn.

From corn starch is prepared glucose, or corn sirup, a thick substance which results from the partial hydrolysis of starch with acid. The acid is neutralized with sodium carbonate, and the liquor resulting from neutralization is filtered. This liquor is evaporated, and again filtered, emerging as a clear thick sirup, which is boiled down even further. It now becomes commercial glucose, a thick syrupy substance about half as sweet as cane sugar, and with little flavor. It is used in making jellies and preserves, and in blending with other sweets such as cane syrup and maple syrup.

From the embryos of corn, corn oil is prepared. Corn oil is used as a cooking oil and also in making soaps and paints. The cake remaining after the oil is pressed from the embryos becomes a stock food.

Corn stalks have been used experimentally in manufacturing paper. However, the abundance of objectionable nonfibrous material will probably prevent any extensive use of the stalks in this industry. The cobs left after shelling the grain are used as a fuel to a slight extent and also in making cob-pipes. The dried husks form a stuffing for a particularly disturbing kind of mattress, and are also used to some extent as a stuffing in upholstery.

The principal varieties of corn include: pod corn, a rarely grown form in which the glumes, lemma and palea of each floret are particularly well-developed, surrounding the kernel; pop corn, in which the sudden explosion of the moisture within the grain turns the latter more or less inside out; sweet corn, characterized by the high sugar content of the grains, and largely grown in home gardens; flint corn, with very hard grains containing a large amount of horny endosperm; and dent corn, so-called because the floury endosperm extends to the end of the kernel and is surrounded laterally by horny endosperm. On maturing the floury endosperm shrinks, causing an obvious dent to appear at the apex of the kernel. Dent corn is raised most extensively. See Fig. 3.

More detail on corn (maize) can be found in the "Foods and Food Production Encyclopedia" (D.M. Considine, editor), Van Nostrand Reinhold, New York, 1982.

CORN ROOTWORM *(Insecta, Coleoptera)*. Larvae of two species of beetles. The adult of one is yellow-green with six black spots on each wing cover. The larva of this species, the southern corn rootworm, damages the roots and lower stems of various grains and grasses and sometimes kills the plants. The other species is the western corn rootworm. The adult is entirely yellowish-green and the larva burrows inside the roots of corn and stunts or kills the plant. Both beetles are about $\frac{3}{8}$ inch (1 centimeter) long.

The most effective protection against these pests is proper crop rotation. Since the southern rootworm lives on plants other than corn this treatment is supplemented by planting early or late to avoid the most serious attack of the larvae.

CORN SYRUPS. See **Syrups**

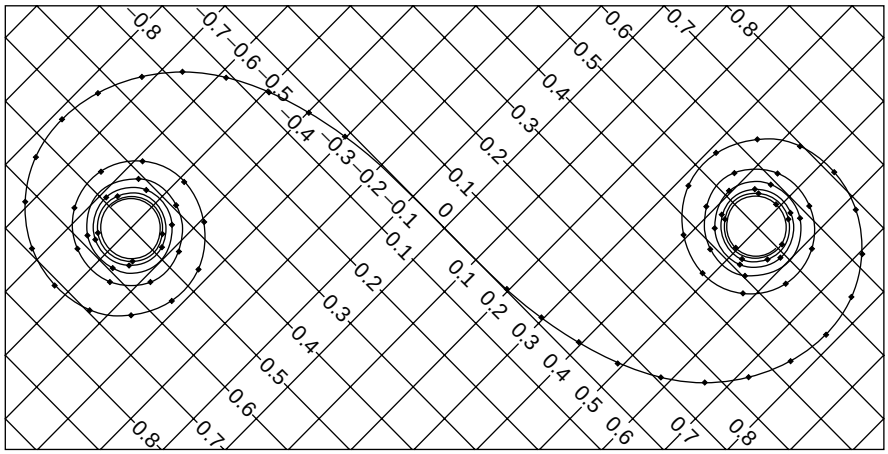

Fig. 1. Cornu spiral.

CORNU SPIRAL. A special kind of plane curve, a spiral obtained by plotting the Fresnel integrals $C(t)$ as abscissa and $S(t)$ as ordinate. Its curvature increases proportionally to the length of arc. Also known as a clothoid, it is of interest in classical optics problems concerned with diffraction. Distances on this curve are used in computing intensities in the pattern resulting from Fresnel diffraction. See Fig. 1.

COROLLARY. A proposition that was incidentally proved in the process of proving another proposition. In current use, a corollary is a consequence of an existing theorem (or proof) which is obvious — so that, at most, a very brief proof need be stated for it.

CORONA. A set of one or more colored rings of small angular radii concentrically surrounding the the sun, moon, or other light source when veiled by a thin cloud.

The corona can be distinguished from the halo of 22° due to its much smaller angular radius, which is often only a few degrees, and by its color sequence, which is from bluish white on the inside to reddish on the outside, the reverse of that in the 22° halo. Further, the color sequence of the corona can be repeated. Fraunhofer diffraction theory is often used to provide an approximate description of the corona. This theory predicts that the center of the corona is essentially white and that the radius of a ring of a particular color is approximately inversely proportional to the drop radius. Consequences of this are that the rings are most discernible and have the purest colors when the droplets in a particular portion of a cloud are nearly uniform in size (mono disperse); the rings are most nearly circular if the droplets that produce different portions of the corona are nearly the same size (spatial homogeneity); rings are caused by droplets with a radius of less than about 15 μm (the rings from larger droplets are washed out by the angular width of the sun). When there is a broad range of droplet sizes, the rings are distinct, the colors faint, and the phenomenon is often called an aureole. Although it is possible for colorful coronas to be produced by ice crystals, usually the broad range of sizes and shapes of crystals precludes this. Similarly, coronas are rarely produced by dust due to the broad range of particle sizes normally present, but rare observations, such as Bishop's rings, have been reported.

CORONA AUSTRALIS (southern crown). A southern constellation located near Sagittarius.

CORONA BOREALIS (northern crown). A northern constellation located between Hercules and Bootes, the grouping of stars essentially forming a semicircle.

CORONA DISCHARGE. A luminous, and often audible, electric discharge that is intermediate in nature between a spark discharge (with, usually, its single discharge channel) and a point discharge (with its diffuse, quiescent, and nonluminous character). Also called *brush discharge* and **corposant**.

It occurs from objects, especially pointed ones, when the electric field strength near their surfaces attains a value near 1×10^5 V m^{-1}. Aircraft flying through active electrical storms often develop corona discharge streamers from antennas and propellers, and even from the entire fuselage and wing structure. So-called precipitation static results. It is seen also during stormy weather, emanating from the yards and masts of ships at sea. See also **Saint Elmo's Fire**.

CORONAGRAPH. An instruments for photographing the corona and prominences of the sun at times other than at solar eclipse. An occulting disk is used to block out the image of the body of the sun in the focal plane of the objective lens. The light of the corona passes the occulting disk and is focused on a photographic film. Great care must be taken to avoid light scattered from the atmosphere and the lenses, and from reflections in the tube of the instrument. The coronograph is used with a narrow-band polarizing filter or with a spectroscope. See also **Sun (The)**.

CORONAL HOLES. Coronal holes are large regions in the corona that are less dense and cooler than surrounding areas. The open structure of their magnetic field allows a constant flow of high-density plasma to stream out of the holes. There is an increase in the intensity of the solar wind effects on Earth when a coronal hole faces us. See also **Heliosphere**; and **Solar Wind**.

The ominous, dark shapes haunting the left side of the Sun (Fig. 1.) are coronal holes — low density regions extending above the surface where the solar magnetic field opens freely into interplanetary space. Studied extensively from space since the 1960s in ultraviolet and x-ray light, coronal holes are known to be the source of the high-speed solar wind, atoms and electrons which flow outward along the open magnetic field lines. During periods of low activity, coronal holes typically cover regions just above the Sun's poles. These coronal holes, however, have just moved into view near the Sun's equator, and particles escaping them have already caused notable aurora here on Earth. Coronal holes like this one may last for a few solar rotations before the magnetic fields shift and change configurations. Shown in false-color, this picture of the Sun on March 9 was made in extreme ultraviolet light by the EIT instrument on board the space-based SOHO observatory. See also **Sun (The)**.

CORONAL MASS EJECTIONS. Large flares are often associated with huge ejections of mass from the Sun, although the association is not clear.

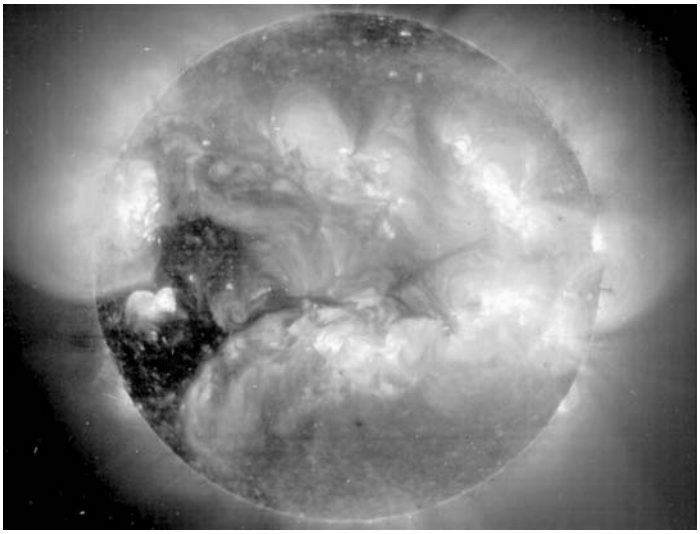

Fig. 1. Coronal Holes on the Sun. (*photo courtesy of SOHO–EIT Consortium, ESA, and NASA*).

These coronal mass ejections (CMEs) are balloon-shaped bursts of solar wind rising above the solar corona, expanding as they climb. Solar plasma is heated to tens of millions of degrees, and electrons, protons, and heavy nuclei are accelerated to near the speed of light. The super-heated electrons from CMEs move along the magnetic field lines faster than the solar wind can flow. Rearrangement of the magnetic field, and solar flares may result in the formation of a shock that accelerates particles ahead of the CME loop. Each CME releases up to 100 billion kg (220 billion lb) of this material, and the speed of the ejection can reach 1,000 km/second (621 mi/second) in some flares. Solar flares and CMEs are currently the biggest "explosions" in our solar system, roughly approaching the power in ONE BILLION hydrogen bombs!

Fast CMEs occur more often near the peak of the 11-year solar cycle, and can trigger major disturbances in Earth's magnetosphere, known as space weather.

CORONARY ARTERY DISEASE (CAD). Coronary artery disease (CAD) occurs when the arteries that supply blood to the heart muscle (the coronary arteries) become hardened and narrowed. The arteries harden and narrow due to buildup of a material called *plaque* (plak) on their inner walls. The buildup of plaque is known as atherosclerosis. As the plaque increases in size, the insides of the coronary arteries get narrower and less blood can flow through them. Eventually, blood flow to the heart muscle is reduced, and, because blood carries much-needed oxygen, the heart muscle is not able to receive the amount of oxygen it needs. Also called *coronary heart disease*, *heart disease* and *ischemic heard disease*. Reduced or cutoff blood flow and oxygen supply to the heart muscle can result in:

- *Angina*: Angina is chest pain or discomfort that occurs when the heart does not get enough blood. See also **Angina**.
- *Heart Attack*: A heart attack happens when a blood clot develops at the site of plaque in a coronary artery and suddenly cuts off most or all blood supply to that part of the heart muscle. Cells in the heart muscle begin to die if they do not receive enough oxygen-rich blood. This can cause permanent damage to the heart muscle. See also **Coronary Thrombosis**.

Over time, CAD can weaken the heart muscle and contribute to:

- *Heart Failure*: In heart failure, the heart can't pump blood effectively to the rest of the body. Heart failure does not mean that the heart has stopped or is about to stop. Instead, it means that the heart is failing to pump blood the way that it should. See also **Congestive Heart Failure (CHF)**.
- *Arrhythmias*: Arrhythmias are changes in the normal beating rhythm of the heart. Some can be quite serious. See also **Arrhythmias (Cardiac)**.

CAD is the most common type of heart disease. It is the leading cause of death in the United States in both men and women. See also **Heart and Circulatory System (Physiology)**; and **Ischemic Heart Disease**.

Causes

CAD is caused by atherosclerosis (the thickening and hardening of the inside walls of arteries). Some hardening of the arteries occurs normally as a person grows older.

In atherosclerosis, plaque deposits build up in the arteries. Plaque is made up of fat, cholesterol, calcium, and other substances from the blood (Fig. 1). Plaque buildup in the arteries often begins in childhood. Over time, plaque buildup in the coronary arteries can:

- Narrow the arteries. This reduces the amount of blood and oxygen that reaches the heart muscle.
- Completely block the arteries. This stops the flow of blood to the heart muscle.
- Cause blood clots to form. This can block the arteries that supply blood to the heart muscle.

Plaque in the arteries can be:

- Hard and stable. Hard plaque causes the artery walls to thicken and harden. This condition is associated more with angina than with a heart attack, but heart attacks frequently occur with hard plaque.
- Soft and unstable. Soft plaque is more likely to break open or to break off from the artery walls and cause blood clots. This can lead to a heart attack.

CAD Risk Factors

About 13 million people in the United States have coronary artery disease (CAD). It is the leading cause of death in both men and women. Each year, more than half a million Americans die from CAD.

Several factors increase the risk of developing CAD. The more risk factors you have, the greater chance you have of developing CAD. Some CAD risk factors, such as age, can't be modified, but others can.

Risk Factors That Cannot Be Modified.

- *Age.* As you get older, your risk for CAD increases.
  - In men, risk increases after age 45.
  - In women, risk increases after age 55.
- *Family History of Early Heart Disease.*
  - Heart disease diagnosed before age 55 in father or brother.
  - Heart disease diagnosed before age 65 in mother or sister.

Risk Factors That Can Be Modified.

- High blood cholesterol
- High blood pressure
- Cigarette smoking
- Diabetes
- Overweight or obesity
- Lack of physical activity

Other Potential Risk Factors.

Scientists continue to study other potential risk factors for developing CAD.

According to some research studies, high blood levels of a substance called *C-reactive protein* (CRP) may be associated with an increased risk of developing CAD and having a heart attack. CRP is a protein in the blood that shows the presence of inflammation. Inflammation is the body's response to injury or infection. CRP levels rise when there is inflammation. The inflammation process appears to contribute to the growth of plaque in arteries.

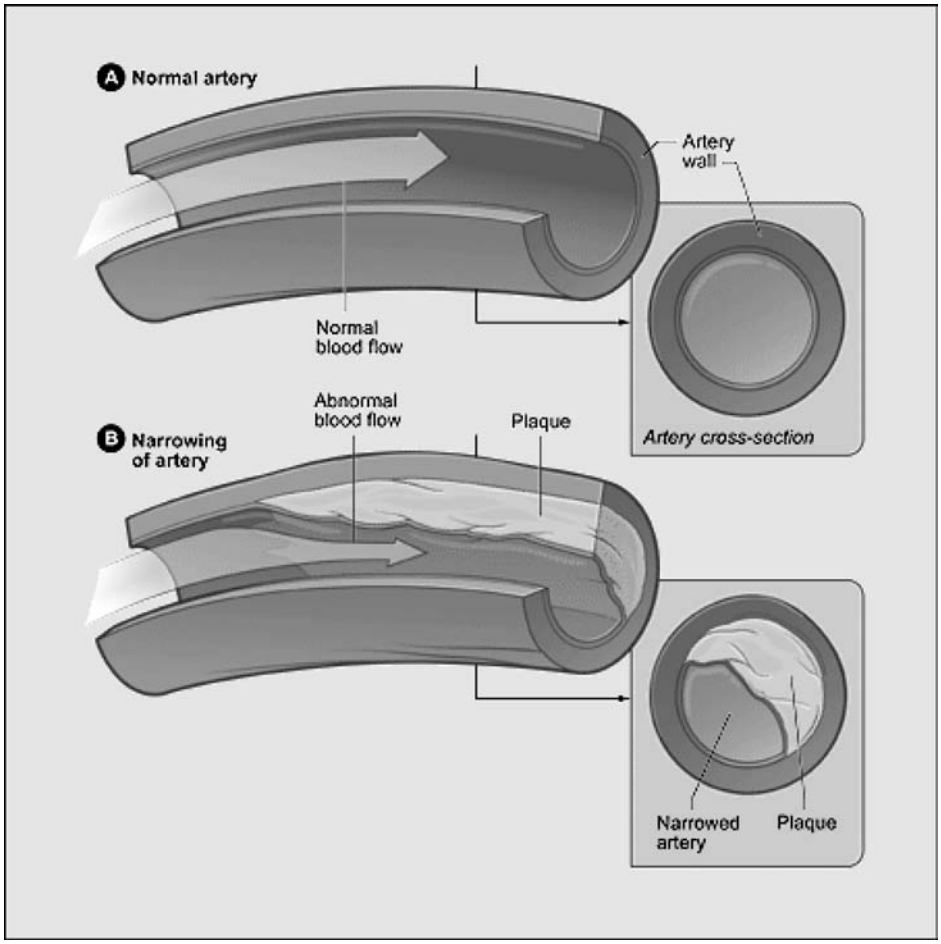

Fig. 1. The illustration shows a normal artery with normal blood flow (Figure A) and an artery containing plaque buildup (Figure B).

Research is underway to find out if reducing inflammation and lowering CRP levels can also reduce the risk of developing CAD and having a heart attack.

Signs and Symptoms

The most common symptoms of coronary artery disease (CAD) are:

- Chest pain or chest discomfort (angina) or pain in one or both arms or in the left shoulder, neck, jaw, or back
- Shortness of breath

The severity of symptoms varies widely. Symptoms may become more severe as coronary arteries become narrower due to the buildup of plaque (atherosclerosis).

In some people, the first sign of CAD is a heart attack. A heart attack happens when plaque in a coronary artery breaks apart, causing a blood clot to form and block the artery.

Diagnosis

There is no single test to diagnose coronary artery disease (CAD). Your physician will ask about your medical history and your family's medical history, assess your risk factors, and do a physical exam and several tests. These procedures are used to:

- Decide if you have CAD
- Determine the extent and severity of the disease
- Rule out other possible causes of your symptoms

Based on the results of these procedures, your doctor may order one or more of the following tests:

- EKG *(Electrocardiogram)*: This test measures the rate and regularity of your heartbeat.
- *Echocardiogram*: This test uses sound waves to create a moving picture of your heart. Echocardiogram provides information about the size and shape of your heart and how well your heart chambers and valves are functioning. The test also can identify areas of poor blood flow to the heart, areas of heart muscle that are not contracting normally, and previous injury to the heart muscle caused by poor blood flow.
  There are several different types of echocardiograms, including a stress echocardiogram. During this test, an echocardiogram is done both before and after your heart is stressed either by having you exercise or by injecting a medicine into your bloodstream that makes your heart beat faster and work harder. A stress echocardiogram is usually done to find out if you have decreased blood flow to your heart (coronary artery disease).
- *Stress Test*: Some heart problems are easier to diagnose when your heart is working harder and beating faster than when it's at rest. During stress testing, you exercise (or are given medicine if you are unable to exercise) to make your heart work harder and beat faster while heart tests are performed.
  During exercise stress testing, your blood pressure and EKG readings are monitored while you walk or run on a treadmill or pedal a bicycle. Other heart tests, such as nuclear heart scanning or echocardiography, also can be done at the same time. These would be ordered if your doctor needs more information than the exercise stress test can provide about how well your heart is working.
  If you are unable to exercise, a medicine can be injected through an intravenous line (IV) into your bloodstream to make your heart work harder and beat faster, as if you are exercising on a treadmill or bicycle. Nuclear heart scanning or echocardiography is then usually done.
  During nuclear heart scanning, radioactive tracer is injected into your bloodstream, and a special camera shows the flow of blood through your heart and arteries. Echocardiography uses sound waves to show blood flow through the chambers and valves of your heart and to show the strength of your heart muscle.
  Your doctor also may order two newer tests along with stress testing if more information is needed about how well your heart works. These new tests are magnetic resonance imaging (MRI) and positron emission

tomography (PET) scanning of the heart. MRI shows detailed images of the structures and beating of your heart, which may help your doctor better assess if parts of your heart are weak or damaged. PET scanning shows the level of chemical activity in different areas of your heart. This can help your doctor determine if enough blood is flowing to the areas of your heart. A PET scan can show decreased blood flow caused by disease or damaged muscles that may not be detected by other scanning methods.

- *Chest X Ray*: A chest x ray takes a picture of the organs and structures inside the chest. These include the heart, lungs, and blood vessels.
- *Cardiac Catheterization*: A thin, flexible tube is passed through an artery in the groin or arm to reach the coronary arteries. The tube allows your doctor to examine the inside of your arteries to see if there is any blockage. Your doctor also can determine the pressure and blood flow in the heart's chambers, collect blood samples from the heart, and examine the arteries of the heart by X ray.
- *Coronary Angiography*: This test is usually performed along with cardiac catheterization. A dye that can be seen by x ray is injected through the catheter into the coronary arteries. The doctor can see the flow of blood through the heart and the location of blockages.
- *Nuclear Heart Scan*: This test provides your doctor with moving pictures of the blood passing through your heart's chambers and arteries and shows the level of blood flood to the heart muscle. A small amount of a radioactive tracer is injected into your bloodstream through a vein, usually in your arm. A special camera is placed in front of your chest to show where the tracer lights up in healthy heart muscle and where it doesn't light up (in heart muscle that has been damaged or has a blocked artery).

  There are different types of nuclear heart scans. Most scans have two phases — taking pictures of the heart at rest and while it is beating faster (called a stress test), although sometimes only a rest scan is done. Many heart problems show up more clearly when your heart is stressed than when it is at rest. By comparing the nuclear heart scan of your heart at rest to your heart at "stress," your doctor can determine if your heart is functioning normally or not.
- Electron beam computed tomography. This test identifies and measures calcium buildup in and around the coronary arteries.

A doctor may also order the following blood tests:

- A fasting glucose test to check your blood sugar level
- A fasting lipoprotein profile to check your cholesterol levels.

Treatment

Treatment for coronary artery disease (CAD) may include lifestyle changes, medicines, and special procedures. The goals of treatment are to:

- Relieve symptoms
- Slow or stop atherosclerosis by controlling or reducing the risk factors
- Lower the risk of having blood clots form, which can cause a heart attack
- Widen or bypass clogged arteries

Lifestyle Changes. Making lifestyle changes can help treat CAD. For some people, these changes may be the only treatment needed:

- Eat a healthy diet to prevent or reduce high blood pressure and high blood cholesterol and to maintain a healthy weight
- Quit smoking, if you smoke
- Exercise, as directed by your doctor
- Lose weight, if you are overweight or obese
- Reduce stress

Medicines. In addition to making lifestyle changes, medicines may be needed to treat CAD. Some medicines decrease the workload on the heart and relieve symptoms of CAD. Others decrease the chance of having a heart attack or dying suddenly and prevent or delay the need for a special procedure (for example, angioplasty or bypass surgery).

Several types of medicine are commonly used to treat CAD.

Cholesterol-Lowering Medicines. Several types of medicine are used to treat high cholesterol levels. Your physician will decide which type of medicine is right for you. He or she may prescribe more than 1 of these drugs at a time because combinations of these medicines can be more effective.

Statins (also called *HMG-CoA reductase inhibitors*) slow down your body's production of cholesterol. These drugs also remove cholesterol buildup from your arteries (blood vessels). Examples of statins include atorvastatin (brand name: Lipitor), fluvastatin (brand name: Lescol), lovastatin (brand names: Altocor, Mevacor), pravastatin (brand name: Pravachol), rosuvastatin (brand name: Crestor) and simvastatin (brand name: Zocor).

Resins (also called *bile acid sequestrants*) help lower your LDL cholesterol level. Some examples of bile acid sequestrants include cholestyramine (brand names: Prevalite, Questran), colesevelam (brand name: Welchol) and colestipol (brand name: Colestid).

Fibrates (also called *fibric acid derivatives*) help lower your cholesterol by reducing the amount of triglycerides (fats) in your body and by increasing your level of "good" cholesterol (also called HDL, or high-density lipoprotein). Some examples of fibrates include fenofibrate (brand names: Antara, Lofibra, Tricor) and gemfibrozil (brand name: Lopid).

Niacin (also called *nicotinic acid*) is a B vitamin. When given in large doses, it can lower your levels of triglycerides and LDL cholesterol, and increase your HDL cholesterol level. Even though you can buy niacin without a prescription, you should not take it to lower your cholesterol unless your doctor prescribes it for you. It can cause serious side effects.

Cholesterol absorption inhibitors help lower your cholesterol by reducing the amount that is absorbed by your intestines. Ezetimibe (brand name: Zetia) is a cholesterol absorption inhibitor. This type of medicine is often given in combination with a statin. The combination of ezetimibe and simvastatin (brand name: Vytorin) is an example.

Anticoagulants. Anticoagulants decrease the clotting ability of the blood and therefore help to prevent harmful clots from forming in the blood vessels. These medicines are sometimes called blood thinners, although they do not actually thin the blood. They also will not dissolve clots that already have formed, but they may prevent the clots from becoming larger and causing more serious problems. They are often used as treatment for certain blood vessel, heart, and lung conditions. See also **Anticoagulants**

Aspirin. Aspirin, and other antiplatelet medicines, help to prevent clots from forming in your arteries and blocking blood flow. Blood contains small cells called platelets which clump together to form clots. Antiplatelet medicines reduce the ability of platelets to form clots. Aspirin may not be appropriate for some people because it increases the risk of bleeding. See also **Aspirin**

ACE (Angiotensin-Converting Enzyme) Inhibitors. ACE inhibitors belong to the class of medicines called high blood pressure medicines (antihypertensives). They are used to treat high blood pressure (hypertension).

High blood pressure adds to the workload of the heart and arteries. If it continues for a long time, the heart and arteries may not function properly. This can damage the blood vessels of the brain, heart, and kidneys, resulting in a stroke, heart failure, or kidney failure. High blood pressure may also increase the risk of heart attacks. These problems may be less likely to occur if blood pressure is controlled.

The ACE inhibitor drugs include Benazepril (brand name: Lotensin), Captopril (brand name: Capoten), Enalapril/Enalaprilat (brand name: Vasotec oral and injectable), Fosinopril (brand name: Monopril), Lisinopril (brand name: Zestril and Prinivil), Moexipril (brand name: Univasc), Perindopril (brand name: Aceon), Quinapril (brand name: Accupril), Ramipril (brand name: Altace), and Trandolapril (brand name: Mavik).

Lisinopril, captopril, ramipril, and trandolapril are used in some patients after a heart attack. After a heart attack, some of the heart muscle is damaged and weakened. The heart muscle may continue to weaken as time goes by. This makes it more difficult for the heart to pump blood. Lisinopril use may be started within 24 hours after a heart attack to increase survival rate. Captopril, ramipril, and trandolapril help slow down the further weakening of the heart.

Captopril is also used to treat kidney problems in some diabetic patients who use insulin to control their diabetes. Over time, these kidney problems may get worse. Captopril may help slow down the further worsening of kidney problems. In addition, some ACE inhibitors are used to treat congestive heart failure or may be used for other conditions as determined by a doctor.

The exact way that these medicines work is not known. They block an enzyme in the body that is necessary to produce a substance that causes blood vessels to tighten. As a result, they relax blood vessels. This lowers blood pressure and increases the supply of blood and oxygen to the heart.

Beta Blockers. Beta-adrenoreceptor blocking drugs, more commonly called *beta-blockers* are used to treat high blood pressure (hypertension), congestive heart failure (CHF), abnormal heart rhythms (arrhythmias), and chest pain (angina). Beta-blockers are sometimes used in heart attack patients to prevent future heart attacks.

Beta-blockers work by blocking the action of noradrenaline at special sites (receptors) in arteries and the heart muscle. Noradrenaline is a chemical that transmits messages between nerves and muscles, or between one set of nerves and another. By blocking its action, beta-blockers can cause arteries to widen and can slow the action of the heart and decrease its force of contraction. This results in a fall in blood pressure and reduced work by the heart.

Commonly used brand names in the United States are: Betapace (brand name: sotalol), Blocadren (brand name: timolol), Brevibloc (brand name: esmolol), Cartrol (brand name: carteolol), Coreg (brand name: carvedilol), Corgard (brand name: nadolol), Inderal (brand name: propranolol), Inderal-LA (brand name: propranolol), Kerlone (brand name: betaxolol), Levatol (brand name: penbutolol), Lopressor (brand name: metoprolol), Normodyne (brand name: labetalol), Sectral (brand name: acebutolol), Tenormin (brand name: atenolol), Toprol-XL (brand name: metoprolol), Trandate (brand name: labetalol), Visken (brand name: pindolol), and Zebeta (brand name: bisoprolol).

Calcium Channel Blockers. Calcium channel blockers are also called *calcium antagonists* or *calcium blockers*. Calcium channel blockers are a class of drugs that block the entry of calcium into the muscle cells of the heart and the arteries. It is the entry of calcium into these cells that causes the heart to contract and arteries to narrow. By blocking the entry of calcium, CCBs decrease contraction of the heart and dilate (widen) the arteries.

In order to pump blood, the heart needs oxygen. The harder the heart works, the more oxygen it requires. Angina (heart pain) occurs when the supply of oxygen to the heart is inadequate for the amount of work the heart must do. By dilating the arteries, CCBs reduce the pressure in the arteries. This makes it easier for the heart to pump blood, and, as a result, the heart needs less oxygen. By reducing the heart's need for oxygen, CCBs relieve or prevent angina. CCBs also are used for treating high blood pressure because of their blood pressure-lowering effects. CCBs also slow the rate at which the heart beats and are therefore used for treating certain types of abnormally rapid heart rhythms.

CCBs are used for treating high blood pressure, angina, and abnormal heart rhythms (e.g., atrial fibrillation). They also may be used after a heart attack, particularly among patients who cannot tolerate beta-blocking drugs, have atrial fibrillation, or require treatment for their angina. (Unlike beta blockers, CCBs have not been shown to reduce mortality or additional heart attacks after a heart attack.) CCBs are as effective as ACE inhibitors in reducing blood pressure, but they may not be as effective as ACE inhibitors in preventing the kidney failure of high blood pressure or diabetes.

CCBs differ in their duration of action, the process by which they are eliminated from the body, and, most importantly, in their ability to affect heart rate and contraction. Some CCBs (e.g., amlodipine) have very little effect on heart rate and contraction so they are safer to use in individuals who have heart failure or bradycardia (a slow heart rate). Verapamil and diltiazem have the greatest effects on the heart and reduce the strength and rate of contraction. Therefore, they are used in reducing heart rate when the heart is beating too fast.

The CCBs that have been approved for use in the US include nisoldipine (brand name: Sular), nifedipine (brand name: Adalat, Procardia), nicardipine (brand name: Cardene), bepridil (brand name: Vascor), isradipine (brand name: Dynacirc), nimodipine (brand name: Nimotop), felodipine (brand name: Plendil), amlodipine (brand name: Norvasc), diltiazem (brand name: Cardizem), and verapamil (brand name: Calan, Isoptin).

Nitroglycerin. Nitroglycerin is a vasodilator (a medication that dilates blood vessels) that frequently is used in the management of angina pectoris. Synthesized in 1846, nitroglycerin was first used to treat anginal attacks in 1879. It was granted FDA approval in 1938.

Blood returning from the body in the veins must be pumped by the heart through the lungs and into the arteries against the high pressure in the arteries. In order to accomplish this work, the heart's muscle must produce and use energy ("fuel"). The production of energy requires oxygen. Angina pectoris (angina) or "heart pain" is due to an inadequate flow of blood (and oxygen) to the muscle of the heart. It is believed that all nitrates, including nitroglycerin, correct the imbalance between the flow of blood and oxygen to the heart and the work that the heart must do by dilating the arteries and veins in the body. Dilation of the veins reduces the amount of blood that returns to the heart that must be pumped. Dilation of the arteries lowers the pressure in the arteries against which the heart must pump. As a consequence, the heart works less and requires less blood and oxygen.

Additionally, in patients with angina, nitroglycerin preferentially dilates blood vessels that supply the areas of the heart where there is not enough oxygen, thereby delivering oxygen to the heart tissue that needs it most.

Long-Acting Nitrates. Long-acting nitrates are similar to nitroglycerin but are longer acting and can limit the occurrence of chest pain when used regularly over a long period.

Glycoprotein IIb/IIIa Inhibitors. Glycoprotein IIb/IIIa inhibitors are medicines used in treating patients who have unstable angina, certain types of heart attacks, and in combination with angioplasty with or without stent placement. They are given in combination with heparin or aspirin (blood-thinning agents) to prevent clotting before and during invasive heart procedures.

Glycoprotein IIb/IIIa inhibitors are classified as potent platelet inhibitors. These agents are used to prevent platelets from binding together, which can occur in patients with heart attacks and after angioplasty with or without stent placement.

The following list identifies specific glycoprotein IIb/IIIa inhibitors and their brand names: abciximab (brand name: ReoPro), eptifibatide (brand name: Integrilin), and tirofiban (brand name Aggrastat).

Glycoprotein IIb/IIIa inhibitors are not available in prescription form. They are given only under the supervision of a physician, through an intravenous injection or IV infusion during hospitalization.

Thrombolytic Agents. A drug that is able to dissolve a clot (thrombus) and reopen an artery or vein. Thrombolytic agents may be used to treat a heart attack, stroke, deep vein thrombosis (clot in a deep leg vein), pulmonary embolism, and occlusion of a peripheral artery or indwelling catheter. All thrombolytic agents are serine proteases (they digest protein) and convert plasminogen to plasmin which breaks down the fibrinogen and fibrin and dissolves the clot. See also **Proteases**. Currently available thrombolytic agents include reteplase (r-PA or Retavase), alteplase (t-PA or Activase), urokinase (Abbokinase), prourokinase, anisoylated purified streptokinase activator complex (APSAC), and streptokinase. Also called *clotbuster*, *clot-dissolving medication*, *fibrinolyic agent*.

Special Procedures

Angioplasty. This procedure opens blocked or narrowed coronary arteries. It can improve blood flow to your heart, relieve chest pain, and possibly prevent a heart attack. Sometimes a device called a stent is placed in the artery to keep the artery propped open after the procedure.

Coronary Artery Bypass Surgery. In this procedure arteries or veins from other areas in your body are used to bypass your narrowed coronary arteries. Bypass surgery can improve blood flow to your heart, relieve chest pain, and possibly prevent a heart attack.

Angioplasty or bypass surgery may be used to treat CAD if:

- Medicines and lifestyle changes have not improved your symptoms.
- Your symptoms are getting worse.

Some people may need to have angioplasty or bypass surgery on an emergency basis during a heart attack to limit damage to the heart.

Cardiac Rehabilitation. Your doctor may prescribe cardiac rehabilitation (rehab) for angina or after bypass surgery, angioplasty, or a heart attack. Cardiac rehab, when combined with medicine and surgical treatments, can help you recover faster, feel better, and develop a healthier lifestyle.

Almost everyone with CAD can benefit from cardiac rehab. Rehab has two parts:

- *Exercise Training:* This helps you learn how to exercise safely, strengthen your muscles, and improve your stamina. Your exercise plan will be based on your individual ability, needs, and interests.
- *Education, Counseling, and Training:* This helps you understand your heart condition and find ways to reduce your risk of future heart problems. The cardiac rehab team will help you learn how to cope with the stress of adjusting to a new lifestyle and to deal with your fears about the future.

Summary

About 13 million people in the United States have coronary artery disease (CAD). It is the leading cause of death in both men and women. Each year, more than half a million Americans die from CAD.

CAD occurs when the arteries that supply blood to the heart muscle (the coronary arteries) become hardened and narrowed. The arteries harden and narrow due to buildup of a material called plaque on their inner walls. The buildup of plaque is known as atherosclerosis. As the plaque increases in size, the insides of the coronary arteries get narrower and less blood can flow through them. Eventually, blood flow to the heart muscle is reduced, and, because blood carries much-needed oxygen, the heart muscle is not able receive the amount of oxygen it needs. Reduced flow of blood and oxygen can lead to problems such as angina (chest pain) and heart attack.

Plaque in the coronary arteries can be hard and stable or soft and unstable. Hard plaque causes the artery walls to thicken and harden. This condition is associated more with angina than with a heart attack. Soft plaque is more likely to break open or break off from the artery walls and cause blood clots. This can lead to a heart attack.

Some of the risk factors for CAD cannot be modified but others can. For example, you can't modify your age and family history. But you can control high blood cholesterol, high blood pressure, cigarette smoking, high blood sugar, overweight or obesity, and lack of physical activity.

Angina is the most common symptom of CAD.

There is no single test to diagnose CAD. Your physician will ask about your medical history and your family's medical history, assess your risk factors, and do a physical exam and several tests. These procedures are used to decide if you have CAD, to determine the extent and severity of the disease, and to rule out other possible causes of your symptoms.

The goals of treatment are to:

- Relieve symptoms
- Slow or stop atherosclerosis by controlling or reducing the risk factors
- Lower the risk of having blood clots form, which can cause a heart attack
- Widen or bypass clogged arteries

Prevention begins with knowing which risk factors you have and taking action. Your chance of developing CAD increases with the number of risk factors you have.

CORONARY OCCLUSION. See **Coronary Thrombosis**.

CORONARY THROMBOSIS. Coronary artery thrombosis (medical condition): Heart attacks or "acute myocardial infarction" (AMI), are very common and also very deadly. The underlying cause of a heart attack is usually "coronary thrombosis", which is a blockage of the blood vessels of the heart. When the heart actually stops in a heart attack, this is called *cardiac arrest*. The most common symptom is chest pain or chest discomfort, but in many cases even the patient is uncertain if they are having a heart attack. If there is any doubt, seek emergency help. However, many cases go undiagnosed even in the emergency department, and this diagnostic error makes AMI the single leading malpractice litigation-related condition. Because the typical profile for AMI in older men (usually over 45), AMI is often underdiagnosed in women or younger adults. In any age patients, AMI can have a variety of presentations, and diagnostic tests such as an EKG may still be normal. Misdiagnoses of AMI include gastrointestinal disorders (26% of misdiagnoses), musculoskeletal pain (21%), or respiratory ailments such as pneumonia or bronchitis (6%).

There are also less serious disorders that are mistakenly believed to be heart attack. A common example are people having a panic attack (anxiety attack) and will rush to emergency in the belief they are dying from a heart attack. Nevertheless, it is important not to take chances, and seek immediate medical attention for any possible heart attack or similar symptoms. See also **Thrombosis**.

Each year, more than a one and a half million individuals in the USA will have an acute myocardial infarction per year; 50% will be fatal and 50% will be a premature/ precocious event. Thus, there are about 750,000 deaths from coronary artery thrombosis per year. Of these coronary thrombotic events, 67% of patients harbor a coagulation blood protein or platelet defect leading to thrombosis. Fifty percent of these coagulation protein or platelet defects will be hereditary, thus emphasizing the importance of defining the presence and type of defect in survivors of acute myocardial infarction. Defining the defect will also allow one to optimize antithrombotic therapy for secondary prevention; this is the best way to make sure appropriate therapy can be delivered to decrease, as much as possible, another (potentially fatal) event. If the defect is hereditary, appropriate family members can be assessed and, when indicated, treated to potentially prevent the first event (heart attack).

Heart Attack. A heart attack occurs when the supply of blood and oxygen to an area of heart muscle is blocked, usually by a clot in a coronary artery (Fig. 1). If treatment is not started quickly, the affected area of heart muscle begins to die. This injury to the heart muscle can lead to serious complications, and can even be fatal. Sudden death from heart attack is most often due to an arrhythmia (irregular heartbeat or rhythm) called *ventricular fibrillation*. If a person survives a heart attack, the injured area of the heart muscle is replaced by scar tissue. This weakens the pumping action of the heart and can lead to heart failure and other complications. Also called *acute myocardial infarction* (AMI); *myocardial infarction* (MI); *acute coronary syndrome*; and *coronary occlusion*. See also **Fibrillation**; and **Heart and Circulatory System (Physiology)**.

Effective treatments for heart attack are available that can decrease the chances of sudden death and long-term complications. To be most effective, these treatments must be given fast — within 1 hour of the start of heart attack symptoms. Acting fast can save your life and limit damage to your heart.

A heart attack is a life-threatening event. Everyone should know the warning signs of a heart attack and how to get emergency help. Many people suffer permanent damage to their hearts or die because they do not get help immediately.

Emergency personnel can often stop arrhythmias with emergency cardiopulmonary resuscitation (CPR), defibrillation (electrical shock), and prompt advanced cardiac life support procedures. If care is sought soon enough, blood flow in the blocked artery can be restored in time to prevent permanent damage to the heart. Most people, however, do not seek medical care for 2 hours or more after symptoms begin. Many people wait 12 hours or longer. See also **Electric Shock**.

Signs and Symptoms. The warning signs and symptoms of a heart attack can include:

- Chest discomfort. Most heart attacks involve discomfort in the center of the chest that lasts for more than a few minutes or goes away and comes back. The discomfort can feel like uncomfortable pressure, squeezing, fullness, or pain. Heart attack pain can sometimes feel like indigestion or heartburn.
- Discomfort in other areas of the upper body. Pain, discomfort, or numbness can occur in one or both arms, the back, neck, jaw, or stomach.
- Shortness of breath. Difficulty in breathing often comes along with chest discomfort, but it may occur before chest discomfort.
- Other symptoms. Examples include breaking out in a cold sweat, having nausea and vomiting, or feeling light-headed or dizzy.

Signs and symptoms vary from person to person. In fact, if you have a second heart attack, your symptoms may not be the same as for the first heart attack. Some people have no symptoms. This is called a *silent* heart attack.

The symptoms of angina (chest pain) can be similar to the symptoms of a heart attack. See also **Angina**.

Diagnosis

Various tests are used in the diagnosis of heart attack.

EKG. An electrocardiogram, also called an EKG or ECG, is a simple test that detects and records the electrical activity of the heart. It is used to detect and locate the source of heart problems.

Electrical signals in the heart trigger heartbeats. These signals start at the top of the heart in an area called the right atrium. The electrical signals travel from the top of the heart to the bottom. They cause the heart muscle to contract as they travel through the heart. As the heart contracts, it pumps blood out to the rest of the body.

An EKG shows how fast the heart is beating. It shows the heart's rhythm (steady or irregular) and where in the body the heartbeat is being recorded.

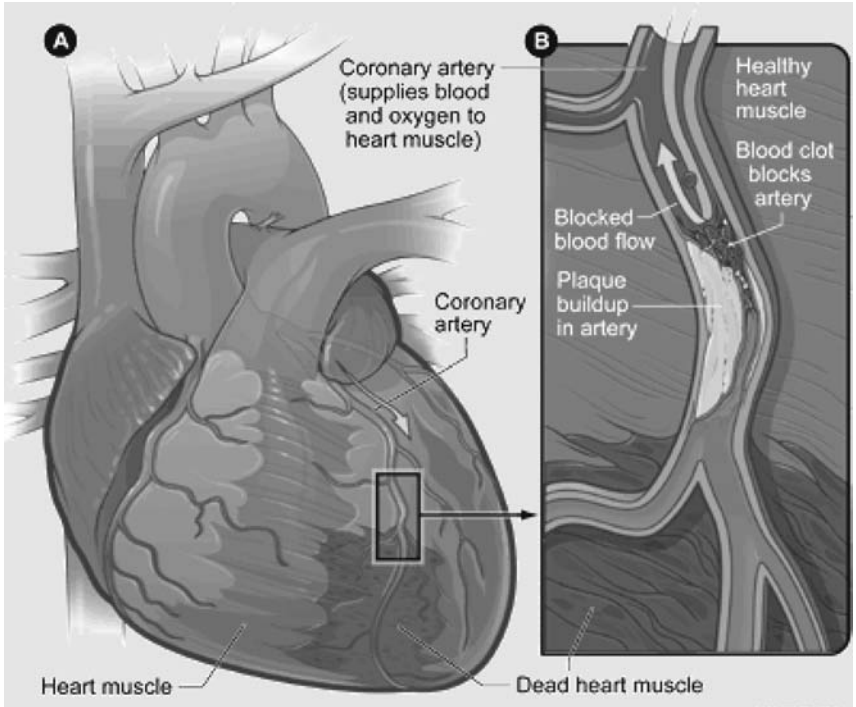

Fig. 1. Figure A is an overview of the heart and coronary artery showing damage (dead heart muscle) caused by a heart attack. Figure B shows a cross-section of the coronary artery with plaque buildup and a blood clot.

It also records the strength and timing of the electrical signals as they pass through each part of the heart.

An EKG is sometimes called a 12-lead EKG (or 12-lead ECG) because the electrical activity of the heart is most often recorded from 12 different places on the body at the same time. See also **Electrocardiography**.

Blood Tests. When cells in the heart die, they release enzymes into the blood. These enzymes are called *markers* or *biomarkers*. Measuring the amount of these markers in the blood can show how much damage was done to your heart. These tests are often repeated at intervals to check for changes. The specific blood tests are:

- Troponin test. This test checks the troponin levels in the blood. This blood test is considered the most accurate to see if a heart attack has occurred and how much damage it did to the heart.
- CK or CK-MB test. These tests check for the amount of the different forms of creatine kinase in the blood.
- Myoglobin test. This test checks for the presence of myoglobin in the blood. Myoglobin is released when the heart or other muscle is injured.

Nuclear Heart Scan (Nuclear Ventriculography). This test uses radioactive tracers (technetium or thallium) to outline heart chambers and major blood vessels leading to and from the heart. A nuclear heart scan shows any damage to your heart muscle. Also called *Cardiac blood pooling imaging*; *Heart scan - nuclear*; *Radionuclide ventriculography* (RNV); and *Multiple gate acquisition scan* (MUGA).

Cardiac Catheterization. Cardiac catheterization is a medical procedure used to diagnose and treat certain heart conditions. A long, thin, flexible tube called a catheter is put into a blood vessel in the arm, upper thigh (groin), or neck and threaded up into the heart. Through the catheter, doctors can perform diagnostic tests and treatments on the heart. Cardiac catheterization is usually performed in a hospital by heart doctors (called *cardiologists*) that specialize in the treatment of heart diseases.

To diagnose some heart conditions, doctors may put a special dye into the catheter to make the inside of the heart and blood vessels show up on X-rays. Doctors may take samples of blood and heart muscle through the tube. They can also treat certain heart problems during this procedure.

Coronary Angiography. Coronary angiography is an X-ray examination of the blood vessels or chambers of the heart. A very small tube (catheter) is inserted into a blood vessel in your groin or arm. The tip of the tube is positioned either in the heart or at the beginning of the arteries supplying the heart, and a special fluid (called a contrast medium or dye) is injected. This fluid is visible by X-ray, and the pictures that are obtained are called *angiograms*.

Treatment

A heart attack is a medical emergency. Delaying treatment can mean lasting damage to your heart or even death. The sooner treatment begins, the better your chances of recovering. Your treatment may begin in the ambulance or in the emergency room and continue in a special area called a coronary care unit (CCU).

If you are having a heart attack, doctors will:

- Work quickly to restore blood flow to the heart
- Continuously monitor your vital signs to detect and treat complications

Restoring blood flow to the heart is vital to prevent or limit damage to the heart muscle and to prevent another heart attack. The main treatments are the use of thrombolytic (clot-busting) drugs and procedures such as angioplasty.

Thrombolytic Drugs (Clot Busters). These drugs are used to dissolve blood clots that are blocking blood flow to the heart. When given soon after a heart attack begins, these drugs can prevent or limit permanent damage to the heart. To be most effective, these drugs must be given within 1 hour after the start of heart attack symptoms.

The current standard thrombolytic drug is t-PA or alteplase (Activase). Others used include reteplase (Retavase), urokinase (Abbokinase), and finally streptokinase (Kabikinase, Streptase). Reteplase and alteplase are equally effective, and the other two are somewhat less effective. Tenecteplase, a newer agent, can be delivered more rapidly than alteplase, and survival rates are similar. Others include lanoteplase and anistreplase (Eminase).

The earlier thrombolytic drugs are administered, the better. The advantages of thrombolytics are highest in the first 90 minutes and are still considerable at three hours. In fact, administering thrombolytics in the ambulance may reduce the risk for death by over 15%. (Not all chest pain victims have heart attacks, however, and not all heart attack patients are candidates for thrombolytics. Such administration should be done only by an experienced health professional.) Administering these drugs more than six hours after symptoms have started adds little or no benefit.

A thrombolytic agent, such as alteplase or tenecteplase, is typically administered with intravenous heparin, an anticoagulant agent. Enoproxin, a form of heparin called *low-molecular weight heparin*, may be more

beneficial than standard heparin. (Heparin, like aspirin, cannot destroy existing blood clots but can prevent clots from reforming after they are broken up.) See also **Heparin**.

Other anticlotting agents are being tested in combination with thrombolytic agents. For example, studies are reporting modest improvements with the addition of glycoprotein IIb/IIIa receptor antagonists to low-dose thrombolytics.

Angioplasty. Coronary angioplasty is a medical procedure used to restore blood flow through a narrowed or blocked artery in the heart. The arteries of the heart (the coronary arteries) can become narrowed and blocked due to buildup of a material called *plaque* on their inner walls. This narrowing reduces the flow of blood through the artery and can lead, over time, to coronary artery disease and heart attack. In angioplasty, a thin tube with a balloon or other device on the end is first threaded through a blood vessel in the arm or groin (upper thigh) up to the site of a narrowing or blockage in a coronary artery. Once in place, the balloon is then inflated to push the plaque outward against the wall of the artery, widening the artery and restoring the flow of blood through it (Fig. 2). Also called *percutaneous coronary intervention*; *percutaneous transluminal angioplasty*; *balloon angioplasty*; and *coronary artery angioplasty*. See also **Coronary Artery Disease (CAD)**

Disease. Angioplasty is used to:

- Relieve chest pain caused by reduced blood flow to the heart.
- Minimize damage to the heart muscle during a heart attack. This damage occurs when blood flow is totally cut off to an area of the heart.

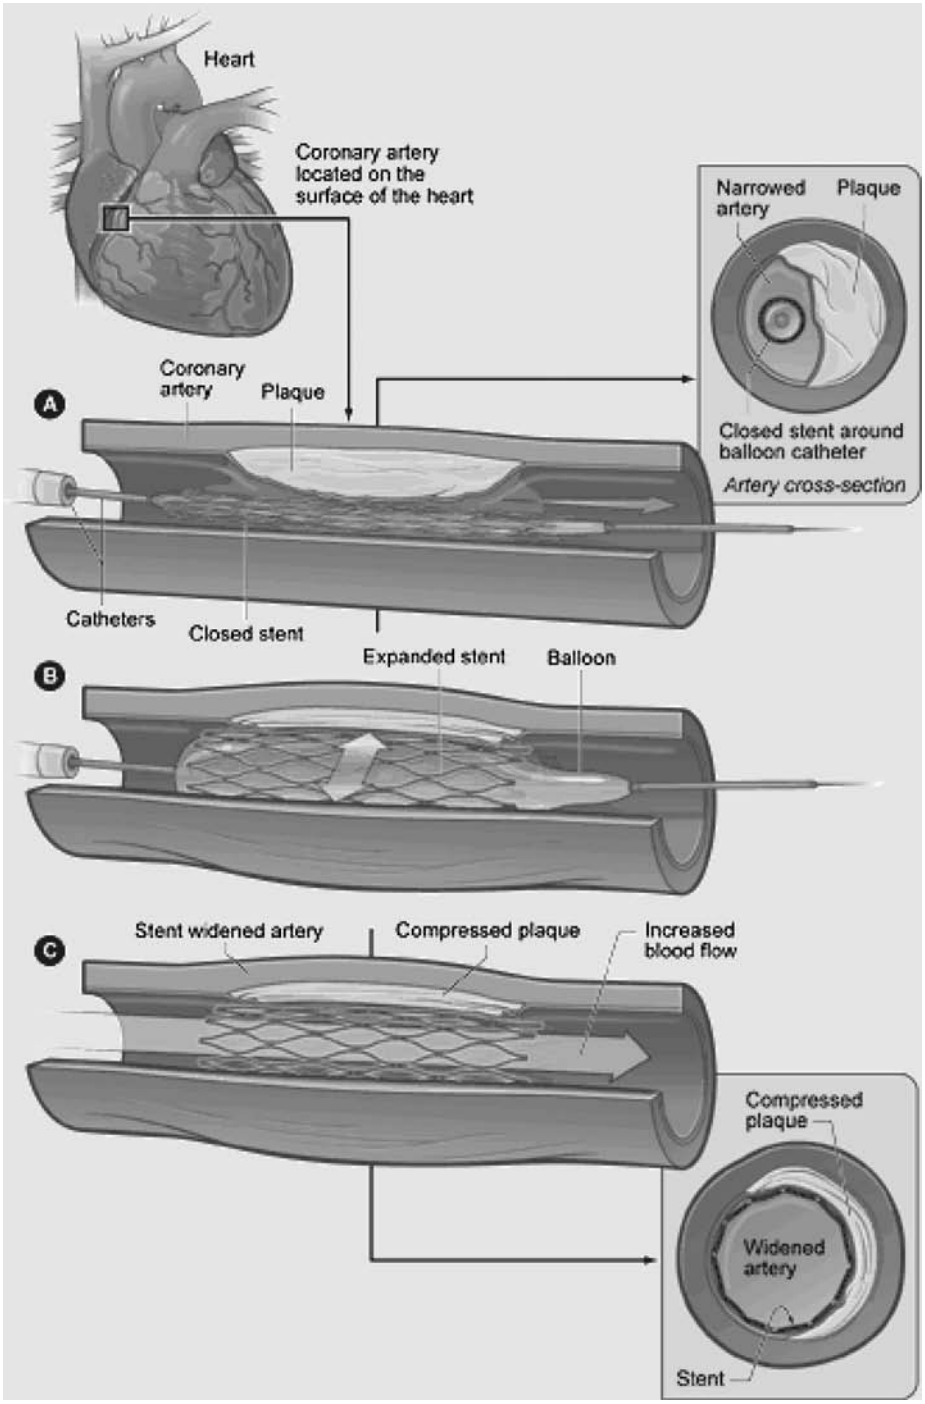

Fig. 2. The illustration shows a cross-section of a coronary artery with plaque buildup. The coronary artery is located on the surface of the heart. Figure A shows the deflated balloon catheter inserted into the narrowed coronary artery. In Figure B, the balloon is inflated, compressing the plaque and restoring the size of the artery. Figure C shows normal blood flow restored in the widened artery.

Angioplasty was first used in 1977. A tiny balloon was used to open or widen narrowed arteries. Since then, new devices and medicines have improved the procedure and made it appropriate for more people. The improvements include:

- Stents. A stent is a tiny mesh tube that looks like a small spring. The stent is inserted in the area where the artery is narrowed to keep it open. Some stents are "coated" with medication to help prevent the artery from closing again. Stents are used in most angioplasties except when an artery is too small for a stent to fit (Fig. 3).
- When a stent is used, in 2 out of 10 people the artery will close again within the first 6 months.
- When a stent is not used, in 4 out of 10 people the artery will close again within the first 6 months.
- Plaque removers. Many kinds of plaque removers exist. They are used to cut away plaque that narrows the inside of the arteries.
- Laser. A laser is used to dissolve or vaporize plaque. First approved in 1992, laser devices are used in many major U.S. medical centers.

Today, angioplasty is performed on more than 1 million people a year in the United States. The procedure is best done:

- By doctors who do at least 75 angioplasties a year
- In hospitals that do at least 400 angioplasties a year

Research on angioplasty continues to:

- Increase its safety
- Prevent the artery from closing again
- Make it an option for more people

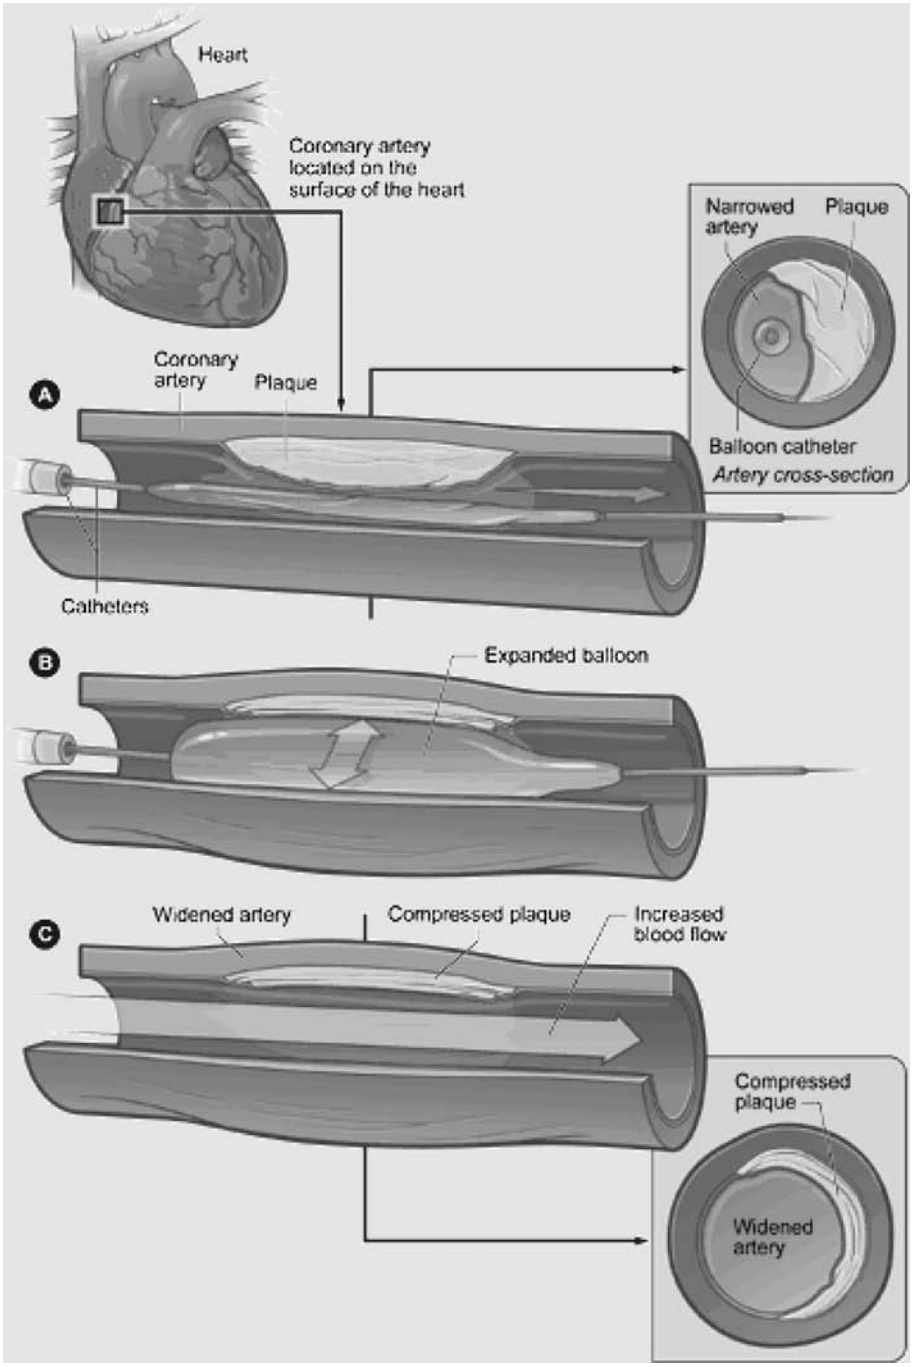

Fig. 3. The illustration shows the placement of a stent in a coronary artery with plaque buildup. The coronary artery is located on the surface of the heart. Figure A shows the deflated balloon catheter and closed stent inserted into the narrowed coronary artery. In Figure B, the balloon is inflated, expanding the stent and compressing the plaque to restore the size of the artery. Figure C shows normal blood flow restored in the stent-widened artery.

Coronary Artery Bypass Surgery. Coronary artery bypass surgery uses arteries or veins from other areas in your body to bypass your blocked coronary arteries.

The CCU is specially equipped with monitors that continuously measure your vital signs. Those that can show signs of complications include:

- EKG (electrocardiogram), which detects problems with the heart rhythm or function
- A blood pressure monitor
- Pulse oximetry, which measures the amount of oxygen in the blood and provides an early warning sign of a low level of oxygen in the blood

Medicines. Several kinds of medicines can be used in treating heart attacks:

- Beta blockers decrease the workload on your heart by slowing your heart rate. This makes your heart beat with less force and lowers your blood pressure. Some beta blockers are also used to relieve angina (chest pain), and they are used in heart attack patients to help prevent additional heart attacks. Beta blockers are also used to correct irregular heartbeat.
- Angiotensin-converting enzyme (ACE) inhibitors lower blood pressure and reduce the strain on your heart. These medicines are used in some patients after a heart attack to increase survival rate and help slow down further weakening of the heart.
- Nitrates, such as nitroglycerin, relax blood vessels and stop chest pain.
- Anticoagulants thin the blood and prevent clots from forming in your arteries.
- Antiplatelet medicines (such as aspirin and clopidigrel) stop platelets from clumping together to form clots. These medicines are given to people who have had a heart attack, have angina, or experience angina after angioplasty. See also **Aspirin**.
- Glycoprotein IIb-IIIa inhibitors are potent antiplatelet medicines given intravenously to prevent clots from forming in your arteries.
- Other medicines may be given to relieve pain and anxiety.
- Some medicines treat arrhythmias (irregular heart rhythms) that often occur during a heart attack.

Oxygen therapy also may be given while you are in the hospital.

Long-Term Treatment

The length of your hospital stay after a heart attack depends on your condition and response to treatment. Most people spend several days in the hospital after a heart attack. While you are in the hospital, your heart will be monitored, and you will receive needed medicines. You will probably have further testing, and you will be treated for any complications that arise.

While you are still in the hospital or after you go home after your heart attack, your doctor may order other tests, such as:

- Echocardiogram. In this test, ultrasound is used to make an image of your heart that can be seen on a video monitor. It shows how well the heart is filling with blood and pumping it to the rest of the body.
- Exercise stress test. Some heart problems are easier to diagnose when the heart is working hard and beating fast. During stress testing, a patient exercises, or is given medicine, to make the heart work harder and beat fast while heart tests are performed. During exercise stress testing, blood pressure and EKG readings are monitored while the patient runs on a treadmill or pedals a bicycle.

In addition to an EKG, other heart tests, such as nuclear heart scanning or echocardiography, can also be done at the same time. During nuclear heart scanning, radioactive dye is injected into the bloodstream, and a special camera shows the flow of blood to the heart muscle. If a person is unable to exercise, a medicine can be injected into the bloodstream to make the heart work harder and beat fast. Nuclear heart scanning or echocardiography is then done.

Two newer tests that are being done with stress testing are magnetic resonance imaging (MRI) and positron emission tomography (PET) scanning of the heart. MRI shows detailed images of the structures and beating of the heart. PET scanning shows blood flow to the heart muscle and areas of damaged heart muscle. See also **Magnetic Resonance Imaging (MRI)**.

After a heart attack, your treatment may include cardiac rehabilitation (see section below) in the first weeks or months, checkups and tests, lifestyle changes, and medicines. You will need to see your doctor for checkups and tests to see how your heart is doing. Your doctor will most likely recommend lifestyle changes, such as quitting smoking, losing weight, changing your diet, or increasing your physical activity.

After a heart attack, most people take daily medicines that may include: aspirin; medicines to lower cholesterol or blood pressure; and other medicines to help reduce the heart's workload.

Always take medicines as your doctor directs.

Cardiac Rehabilitation. Your doctor may prescribe cardiac rehabilitation (rehab) to help you recover from a heart attack and to help prevent another heart attack. Almost everyone who has survived a heart attack can benefit from rehab.

The cardiac rehab team may include:

- Doctors
  - Your family doctor
  - A heart specialist
  - A surgeon
- Nurses
- Exercise specialists
- Physical therapists and occupational therapists
- Dietitians
- Psychologists or other behavior therapists

Rehab has two parts:

- Exercise training helps you learn how to exercise safely, strengthen your muscles, and improve your stamina. Your exercise plan will be based on your individual ability, needs, and interests.
- Education, counseling, and training help you to understand your heart condition and find ways to reduce your risk of future heart problems. The cardiac rehab team will help you learn how to cope with the stress of adjusting to a new lifestyle and to deal with your fears about the future.

CORONA (Sun). The outer envelope of the sun's atmosphere consisting of ionized gases, predominantly hydrogen and helium, at temperatures that exceed one million degrees Kelvin. Also called *solar corona*.

The white light emission observed at solar eclipse or with the coronagraph arises from scattering of photospheric radiation from free electrons in the corona. The shape of the corona varies during the sunspot cycle. At solar minimum the corona has large extensions along the sun's equator, with short brush-like tufts near the poles. At solar maximum the equatorial extensions are much smaller and the corona is more regular in shape. See also **Sun (The)**.

CORONATAE. An order of jellyfishes (*Scyphozoa*) with a lobed margin. Found in the open ocean.

CORPUS CALLOSUM. A broad band of nerve fibers within the brain, connecting the two cerebral hemispheres.

CORPUSCLE. A term applied to many minute bodies: 1. The cells of the blood or lymph. 2. The excretory unit of vertebrates, consisting of a small knot of blood vessels enveloped by a capsule (Renal corpuscle). 3. Bone cells, which are called corpuscles of Purkinje. 4. Many nerve endings including Pacinian or lamellar corpuscles, Grandry's corpuscles, tactile corpuscles. These and all other sensory corpuscles consist of nerve endings enveloped by accessory cells of various forms. They are sensory organs.

CORPUSCULAR COSMIC RAYS. Primary cosmic rays from outer space which consist mainly of protons with energies of 2-20 billion electron volts (Bev). For 1000 protons there are about 80 helium nuclei, about 3 nuclei in the carbon-nitrogen-oxygen range, and 1 or 2 heavier nuclei. The

proton energy may be as high as 105 Bev, and the other nuclei show an energy distribution similar to that of the protons.

CORPUSCULAR THEORY OF LIGHT. The hypothesis, by Sir Isaac Newton, that light consists of a stream of minute particles emitted by luminous bodies at very high velocities, and that the sensation of light, is due to the bombardment of the retina of the eye by these particles. Although this theory was later replaced by the *wave theory of light*, the concept of photons in the modern quantum theory is reminiscent of Newton theory.

CORRASION. This term is applied to the mechanical wearing away of rocks through the agency of running water and the rock fragments it carries in suspension.

CORRECTION TO VACUUM. The correction of wavelengths or of the speed of light or other property as measured in air to the appropriate values *in vacuo*. The index of refraction for air is about 1.000225 but is dependent on the density of the air.

CORRELATION. In general statistical usage correlation or co-relation refers to the departure of two variables from independence. In this broad sense there are several coefficients, measuring the degree of correlation, adapted to the nature of the data, e.g., *association coefficient* for dichotomous material, *contingency coefficient* for more extended classification, *rank correlation* for ranked material and so on. See also **Association (Coefficient of)**; **Contingency Table**; and **Rank Correlation**.

In a narrower sense correlation refers to the degree of dependence of two continuous variables. Given a set of bivariate values $(x_1, y_1) \ldots (x_n, y_n)$ the correlation coefficient is given by

$$r = \frac{\sum_{i=1}^{n}(x_i - \overline{x})(y_i - \overline{y})}{\left\{\sum_{i=1}^{n}(x_i - x)^2 \sum_{i=1}^{n}(y_i - \overline{y})^2\right\}^{1/2}}$$

namely is the covariance of x and y divided by the square root of the product of their variances. It may vary between the limits ± 1. A value of zero results when the variables are independent, but strictly implies independence only when the variables are jointly distributed in the normal (Gaussian) form.

When three or more variables are jointly distributed each pair will have a correlation coefficient expressing in a summary form their degree of correlation. If A is highly correlated with B, and C is also highly correlated with B, there will in general result a correlation between A and C. Attempts to remove such part of this correlation as arises from their common dependence on B leads to the formation of a *partial* correlation coefficient between A and C, the object of which is to measure that part of their correlation that is direct and not merely generated by their relation with a third variable. More complicated forms of partial correlation can arise, e.g., the correlation between X_1 and X_2 when the effect of their correlation with X_3, $X_4 \ldots X_n$ is removed.

The concept is easily generalized to the case where a continuous infinity of observations arises.

An obsolescent expression "correlation ratio" also occurs in older literature. The correlation ratio squared of x on y is given by

$$\eta_{xy}^2 = \sum(\overline{x}_i - \overline{x})^2 \Big/ \sum(x - \overline{x})^2$$

where $\overline{x}_i$ is the mean of x_i for a given y_i, $\overline{x}$ is the mean of all values and the summation in the numerator extends over the values of y_i and that in the denominator over all values. A closely allied ratio rises in the analysis of variance (*q.v.*).

SIR MAURICE KENDALL, International Statistics Institute, London

CORRELATION DETECTION. A method of detection in which a signal is compared, point-to-point, with an internally generated reference. Also called *cross correlation detection*. The output of such a detector is a measure of the degree of similarity of the input and reference signals. The reference signal is constructed in such a way that it is at all times a prediction, or best guess, of what the input signal should be at that time.

CORRELATION TRACKING AND RANGING (COTAR). A non-ambiguous trajectory-measuring system using short-baseline, single-station, continuous-wave phase-comparison measuring two direction cosines and a slant range.

CORRELATION TRACKING AND TRIANGULATION (COTAT). A trajectory measuring system composed of several antenna baselines, each separated by large distances, used to measure direction cosines to an object. From these measurements its space position is computed by triangulation.

CORRELATION TRACKING SYSTEM. A trajectory measuring system utilizing correlation techniques where signals derived from the same source are correlated to derive the phase difference between the signals. This phase difference contains the system data.

CORRELOGRAM. The graph of the autocorrelation coefficient (or the serial correlation) as ordinate against the lag of the coefficient as abscissa. See also **Autocorrelation**.

CORRESPONDENCE PRINCIPLE. The principle that, in the limit of high quantum numbers, the predictions of quantum theory agree with those of classical physics.

CORRODENTIA. An order of minute insects containing the book lice and psocids. They have biting mouths and some species bear four wings. Some are found among plants and on bark and others frequent books and papers, especially in damp buildings.

CORROSION. 1. The electrochemical degradation of metals or alloys due to reaction with their environment; it is accelerated by the presence of acids or bases. In general, the corrodability of a metal or alloy depends upon its position in the activity series (electromotive force series). Corrosion products often take the form of metallic oxides; in the case of aluminum and stainless steel, this is actually beneficial, for the oxide forms a strongly adherent coating, which effectively prevents further degradation. Hence, these metals are widely used for structural purposes. Probably the most familiar kind of corrosion is that of *rusting*. This is but a special case of a general classification known as atmospheric corrosion, wherein the oxygen of the atmosphere reacts with the material in question. Most metals, with exception of the noble metals, such as gold, can be oxidized by atmospheric oxygen. In the usual case, however, water vapor must be present before any appreciable oxidation can take place. With iron, for example, about 40% relative humidity is needed at ordinary temperatures before rusting will occur.

Acidic soils are highly corrosive. Sulfur is a corrosive agent in automative fuels and in the atmosphere (SO_2) as well, and is frequently mentioned in connection with so-called acid rains. Sodium chloride in the air at locations near the sea is strongly corrosive, especially at temperatures above 70 °F (21.1 °C). Copper, nickel, chromium, and zinc are among the more corrosion-resistant metals and are widely used as protective coatings for other metals.

2. The term *corrosion* is also sometimes used in connection with the destruction of body tissues by strong acids and bases.

In a restricted sense, corrosion is considered to consist of the slow chemical and electrochemical reactions between metals and their environments. From a broader point of view corrosion is the slow destruction of any material by chemical agents and electrochemical reactions. This contrasts with *erosion*, which is the slow destruction of materials by mechanical agents. The character of the atmospheres to which materials are exposed may be classified as: rural, urban, industrial, urban-marine, industrial-marine, marine, tropical, and tropical-marine. In addition to these general kinds of environments, corrosion is of particular concern in the environments of chemical, petrochemical, and other processing and manufacturing environments where extremely corrosive substances may be encountered.

Metals Corrosion. The relationships between metals and hydrogen in the activity series are important because in the electrochemical processes of corrosion the discharge of hydrogen ions and the evolution of hydrogen

as a gas is one of the principal cathodic reactions. The facility with which this can occur is determined by such factors as the hydrogen ion concentration (pH) of the electrolyte, the electrical potential of the corrosion cell, and the overvoltage characteristics of the cathodic surface. In a situation sometimes called *concentration cell corrosion*, two solutions of different concentrations will set up an electrical potential between them similar to that produced by a battery. If oxygen is present in the liquid and is continually replenished by contact with the air, then the oxygen concentration in the liquid will remain substantially constant. Any liquid that is contained in small holes or cracks on a metal surface will not be able to obtain oxygen from the main bulk of the solution, so when the supply in the holes and cracks is exhausted, no more oxygen can get in to replace it. Therefore, the oxygen concentration in the cracks is different from that of the main bulk of the solution and a concentration cell is set up. This minute electrical effect is sufficient to make corrosion proceed quite rapidly. A similar cell type of corrosion is that called *galvanic* or *two-metal corrosion*. Two different metals in contact will set up an electrical potential between them. If the two metals are surrounded by an electrolyte so that a closed circuit can be obtained, corrosion takes place. The magnitude of the electrical potential and, therefore, the speed and extent of the corrosion will depend upon the types of metals in each pair. In general, pairs farther apart in the activity series will corrode faster than those close together. See also **Electrochemistry**.

The electrochemical reactions in corrosion of a divalent metal may be written:

Anodic reaction: $M^0 \rightarrow M^{++} + 2$ electrons

At the cathode:
(1) $2\ H^- + 2$ electrons $\rightarrow H_2$ gas
(2) $\frac{1}{2}O_2 + 2\ H^- + 2$ electrons $\rightarrow H_2O$
(3) $O_2 + 2\ H_2O + 2$ electrons $\rightarrow H_2O_2 + 2\ OH^-$
(4) $\frac{1}{2}\ O_2 + H_2O + 2$ electrons $\rightarrow 2\ (OH)^-$

It is evident that oxygen as well as hydrogen plays an important part in metal corrosion. It can accelerate corrosion by participating in cathodic reactions, or it can retard corrosion by forming protective oxides or passive films. The dual effect of oxygen is one of the factors that complicates corrosion processes, including the interpretation of observations of the process and the steps to be taken to avoid corrosion damage.

Forms of Corrosion. (1) *Pitting* resulting from local action currents, as at discontinuities in protective or passive films or under or around deposits that set up concentration cells. (2) *Stress corrosion cracking* resulting from the combined effects of corrosion by a specific environment and either applied or internal static tensile stresses. Depending upon the metal and the environment, the cracks may be either intercrystalline or transcrystalline. (3) *Corrosion fatigue*, resulting from the combined effects of corrosion and cyclic stresses. Racks of this type are characteristically transcrystalline. (4) *Intergranular corrosion* resulting from preferential attack on, or around, a phase or compound that occupies grain boundaries. (5) *Corrasion-corrosion* resulting from the combined effects of corrosion and either abrasion or attrition. The mechanism usually involves local or general removal of otherwise protective corrosion product films. Particular forms are impingement attack due to the effects of high velocity or turbulence in flowing liquids, e.g., salt water in steam condensers, or other heat exchangers, in piping systems, valves, and pumps, among others. A particularly aggressive form is associated with the severe mechanical forces that are characteristic of *cavitation phenomena*. See also **Cavitation**. (6) Uniform attack or general wastage, such as may be caused by the action of strong acids as used for pickling (scale removal) or etching. This is also characteristic of the slow corrosion of durable materials in appropriate environments, such as copper roofing in suburban atmospheres, cupronickel tubes in ships, condensers, Monel-nickel copper alloy racks for pickling steel in sulfuric acid, or stainless steel columns for handling nitric acid.

Metal Corrosion Minimization. In the most recent official assessment of the economic costs of equipment damage arising from corrosion, prepared by the National Commission on Materials Policy (U.S.), it was stated that annual losses in the United States alone are on the order of many billions of dollars.

Some of the means used to combat corrosion losses include:

(1) Use of the right metal in the proper way and in the correct place. Planners tend to look too closely at first costs and not closely enough at maintenance costs; consequently, there are many applications of materials that are of lower first cost, but of severely limited life. For example, in some applications, inexpensive fasteners that will obviously corrode in a few years are used in place of stainless steel or hardened aluminum fasteners that would have cost only a few dollars more at the time of installation. When discussing applications of possible corrosion-resistant materials, it is important to define clearly the parameters of the environment of usage, such as temperature, pressure, humidity, presence of specific chemical agents, presence of living or dead organic materials, and the characteristics of associated electrical magnetic, light, and other radiation fields. Far more needs to be done on the microclimatology of environments and the specifics needed to ameliorate corrosion problems.

(2) Protective coatings — paints, enamels, other metals, oils, greases, among others. One of the more common methods used is zinc-coating, i.e., galvanizing. Galvanized iron wire with a thin layer of zinc applied to it by dipping in molten zinc or by electrical means usually will resist corrosion for an extended period. Cadmium, nickel, tin, and chromium are metals often used as protective coatings, generally applied by electroplating. See also **Electrochemistry**; **Electroplating**; **Galvanizing**; and **Paint and Coatings**.

(3) Inhibitors and neutralizers, i.e., compounds added to the environment in small concentration to form protective films which increase anodic or cathodic polarization or both, or to neutralize some corrosive constituents. For example, it is possible for corrosion to occur at many places in the piping leading to boilers or heaters, but usually it occurs in the boiler itself. The trouble is ordinarily found to be due to an acid condition of the boiler feedwater, or to dissolved oxygen contained in it. The raw water used may be acid from surface pollution or from subsurface drains. Usually this can be detected and readily remedied. A more serious factor is the oxygen dissolved in water. Under the high-temperature conditions existing in the boiler per se, this oxygen becomes extremely active in attacking metal surfaces. The operators of large, high-pressure boilers well know the necessity of removing oxygen from feedwater through the use of deactivators or de-aerators. Corrosion protection of boilers in power plants is effected by installation of ion exchange resin and other purifiers in the feedwater cycle, and by monitoring them by automatic analysis. In still other installations where acidity and oxygen are a problem, neutralizing chemicals with the dosage governed by automated pH and oxygen control systems are effective. Systems of this type are also effectively used to neutralize plant effluents to streams so that water users downstream have a reasonably neutral and clean supply of water. Clean water programs not only are desirable from an environmental standpoint, but also can help in reducing the costs of corrosion.

(4) Drying of air other gases to keep humidity below the level where corrosion becomes serious.

(5) Design of hydraulic systems to avoid excessive velocities or localized turbulence or to maintain a velocity high enough to prevent the accumulation of corrosion products or other deposits that will promote localized corrosion.

(6) Various features of design and operation of structures or equipment to favor rapid drainage and drying, prevent accumulation or concentration of corrosive chemicals in crevices or low spots, hold operating stresses and temperatures within desired limits, eliminate fabricating stresses by appropriate metallurgical treatment, avoid galvanically unfavorable combinations of different metals, and provide protection against stray electrical currents by appropriate insulation and electrical bonding.

(7) Heat-treating metals to leave them in optimum condition to resist corrosion.

(8) Applying protective electrical currents (*cathodic protection*) from sacrificial metals (galvanic anodes) such as zinc, magnesium, or aluminum or from some external source through a graphite, platinum, or other appropriate anode receiving current from a rectifier, generator, or battery. The location of the anodes, the magnitude of the current, and the applied voltage must be engineered so that without wasting current all surfaces that require protection will receive sufficient current to achieve this effect. Too much current may cause damage by the alkali generated by a cathodic reaction or by hydrogen evolved at the cathode, which can destroy protective films or embrittle metals. A current of 1 to 15 milliamperes per square foot (929 square centimeters) is usually required to protect bare steel area; for design purposes, the range is generally narrowed to 3 to 5 milliamperes. The potential required to produce this current flow depends, of course, on the resistivity of the electrolytic path between the electrodes.

Corrosion can also be suppressed by the controlled application of current to the metal as an anode. This is called *anodic protection*. Passivity is

induced and preserved by maintaining the potential of the alloy at, or above, a critical potential in what is called the range of passivity in a potentiostatic diagram. Such diagrams are based on the relationship between applied anodic current density and the corresponding potential in the environment of interest.

When pipes and cables carrying an electric current are underground, they are commonly corroded by electrolytic action from unidirectional electric currents in the ground. Stray current from electric traction equipment is retarded by increasing the resistance of the ground circuit and by reducing the electric resistance of the track. Also, cathodic protection is widely used. An external source of dc voltage is applied so that the protected equipment (pipeline or cable, for example) becomes lower in potential than the soil that surrounds it. Thus, the buried material is the cathode rather than the anode. Usual forms of corrosion can be prevented when the preventive system causes the pipe or metal structure to be 0.25 to 0.30 volt negative with reference to the soil or liquid that may be surrounding it. The negative lead from a small generator, battery, or rectifier is connected to the metal structure; the positive lead to the ground at some distance. Or sacrificial magnesium or zinc rods sunk in the ground may be externally connected to the structure.

Atmospheric Corrosion of Metals and Nonmetals. Taking into consideration the relative order of corrodibility, it is preferable to describe corrosive damage as attributable to certain agents rather than to the indefinite characterization "smoke." Corrosive agents can be placed into four major groups, namely, oxygen and oxidants, acidic materials, salts, and alkalis.

Corrosion attributable to oxygen is deemed to result from the solution of oxygen by a thin film of liquid adjacent to the metallic surface, the transportation of the oxygen through the film, and the subsequent reaction at the surface of the metal. This explains why there is corrosive action even in relatively arid land. In a very dry atmosphere corrosion is, however, markedly reduced.

There are three principal categories of oxidizing agents that occur as air pollutants. These are ozone, nitrogen oxides and nitric acid, and organic peroxide. Many materials that are relatively resistant to attack by the free oxygen of the air are far less resistant to attack by such oxidants and peroxides. These dissolve in the surface film and thus convert metals to their oxides which react readily even with such relatively weak acids as carbonic acid and sulfurous acid. For instance, copper tarnishes rapidly forming the oxide, which dissolves readily in dilute acids.

The acid components given off to the air by the various processes of combustion are sulfur dioxide and sulfurous acid, sulfuric acid, hydrogen sulfide, hydrochloric acid, carbon dioxide and carbonic acid, and tar acids. There is little doubt that the material of greatest importance in respect to atmospheric corrosion in this group is sulfur dioxide. Generally, the total acidity of the atmosphere is closely related to the sulfur dioxide content.

Other soluble acidic components such as sulfuric acid, hydrogen sulfide, hydrochloric acid, nitric acid and the like are all of minor importance. Carbon dioxide and carbonic acid play a significant role in acid decomposition.

One aspect of tar and tar acids should be noted, namely, that these are sticky and cling to the surfaces with which they come in contact. This enables the acids that such tar contains to have a prolonged corrosive action. It also increases the difficulty of removal by rain or wind or other action.

It is common to consider that certain salts have a very corrosive action. This is true in the respect that the corrodibility of marine atmospheres has been shown to be greater than rural, tropical, and urban atmospheres. For example, ammonium sulfate and ammonium chloride being salts of strong acids and a weak base, that is ammonium hydroxide, hydrolyze in water to yield the respective acids. These salts then have a corrosive action, which is due actually to the acid produced in hydrolysis.

Alkalis seldom occur as air pollutants except under industrial conditions. Nevertheless, the corrosive action of alkalis should not be completely ignored. While a number of metals are relatively resistant to acid attack, they have an amphoteric action and can react with alkalis. For instance, aluminum and zinc are in this category and they are subject to corrosive attack by relatively weak alkalis.

Metals exposed to air pollution can be placed into three groups:

1. Metals that corrode rapidly because they do not form completely protective corrosion products. The major metal in this group is iron. It should be noted, however, that iron oxide Fe_2O_3 does have some protective action.
2. Metals that are initially attacked somewhat readily but subsequently become resistant to attack because of the formation of a corrosion-resisting film, which hinders further attack. Among the metals in this group are aluminum, lead, zinc, brass, copper, nickel and magnesium.
3. Metals that are almost completely corrosion resistant, as for instance stainless steel of the 18/8 type, chromium plate products, monel, and gold.

Mention has already been made of the action of oxygen and oxidants on metal. It should be noted that metals react with sulfides, such as hydrogen sulfide, and are subsequently subject to additional slow attack by oxygen and oxidants. Thus, copper reacts to form sulfide and then the basic copper sulfate.

Generally, metals are resistant to attack in dry air; even in pure humid air, corrosion is slight; when, however, air pollutants are present the rate of corrosion will increase measurably, the increase being dependent upon the humidity and the character of the pollutant. Such action may be grouped as follows:

Relative Humidity		Degree of Corrosion
Less than	60	None
More than	60	Slow but definite
	80	Decided increase
Greater than	80	Very high

A factor of note is the settling and adherence of particles on metals. Particles of carbon, ammonium sulfate, and silica cause a marked increase in corrosion, and this is accentuated in atmospheres containing sulfur dioxide. The presence of such hygroscopic particles enhances the adherence of liquid and thus provides for electrochemical attack.

Stone building materials may be placed into relatively resistant and nonresistant categories. The acids of the air, such as sulfuric acid, attack carbonate-bearing stone, such as limestone, converting the calcium carbonate to calcium sulfate. The gypsum formed is dissolved by rainwater, causing pitting. Incrustations may be formed because of the crystallization of soluble salts. These break away in time and leave pitted surfaces. Other types of damage, such as porosity of the stone, are caused by analogous reactions.

Corrosion-Resistant Metals. Some concept of the economic importance of corrosion to the production and consumption of various metals can be gleaned from Table 1. Many mineral commodities are used in more or less direct proportion to steel production. In the case of the United States and many other countries, a large number of the mineral materials important to combating corrosion come from distant sources. That is why many countries maintain a stockpile of such materials, particularly those that are regarded as critical or strategic. In the United States, 93 materials are officially classified for defense purposes as basic stockpile commodities. Seventy-nine of these are metals and minerals, including nearly every one of the metals with important corrosion-resistant properties.

The possible use of low-grade, currently noncommercial, mineral deposits, requires constant consideration. For example, chromium has been recognized as an important strategic material ever since World War I. Over the years, the U.S. government, through the U.S. Geological Survey and the Bureau of Mines, has discovered and carefully defined numerous domestic chromium deposits. The Bureau of Mines in its metallurgical laboratories has produced acceptable chrome concentrates from these deposits as well as acceptable ferrochromium chemicals. Current Bureau of Mines research includes recovering chromium, nickel, and cobalt from laterite deposits, both domestic and from other countries, and also from flue dusts, plating wastes, and other residues.

Corrosion Monitoring. Combatting corrosion in continuous processing plants, which may be scheduled for quite infrequent but thorough equipment checking and maintenance, is particularly difficult. Process downtime costs for a large unit may be several hundred thousand dollars per day in terms of lost production. To avoid excessive downtime for checking and still control the effects of corrosion (personnel and equipment safety, product quality and throughput rates, etc.) requires means to measure the status and rate of corrosion that may be taking place within the equipment. The design of corrosion monitors is among the most recent developments in overall process instrumentation. For obvious reasons, such on-line corrosion testing must be of a nondestructive nature.

TABLE 1. APPLICATIONS OF CORROSION-RESISTANT METALS

Metal	Corrosion Resistance Use	Consumption	
		For Corrosion Applications	Percent of All Uses of Metal
Nickel	Alloying, 34%; high-temperature oxidation resistance, 26%; plating, 13%	144,000 MT	73
Chromium	Alloying, 57%; coatings and plating, 7%	306,000 MT	64
Titanium	Coatings, 51%; alloying, 1%	243,000 MT	52
Cadmium	Plating	2,520 MT	45
Gold	Plating and alloying	50,000 kg	35
Zinc	Galvanizing, 32%; coatings and sacrificial anodes, 3%	432,000 MT	35
Tin	Plating, tinning	19,800 MT	34
Tantalum	Alloying, 16%; cladding, 12%; high-temperature oxidation resistance, 5%	1,935 MT	33
Rare earths	Alloying	3,600 MT	30
Platinum	Resistance to chemical attack	13,375 kg	27
Silver	Alloying	1,370 kg	26
Columbium (Niobium)	Alloying; high-temperature oxidation resistance	630 MT	25
Iron oxide pigments	Coatings	30,600 MT	25
Copper	Alloying and plumbing	370,000 MT	18
Molybdenum	Alloying; coating	4,860 MT	18
Cobalt	Alloying; high-temperature oxidation resistance	1,530 MT	17
Magnesium	Alloying; sacrificial anodes	14,400 MT	15
Zirconium	Alloying; chemical resistance	340 MT	15
Thorium	Alloying	31 MT	12
Hafnium	Alloying	3 MT	11
Beryllium	Alloying	4 MT	10
Lead	Pigments and plating, 8%; cable covering, 1%	108,000 MT	9
Indium	Coatings	1,555 kg	8
Aluminum	Alloying; coatings; cladding	225,000 MT	5
Manganese	Alloying; cladding	45,000 MT	4

MT = metric ton; kg = kilogram

In one type of monitor, changes in electrical resistance of a measuring element or probe relate to corrosion rate. The measuring element may be a wire, tube, or strip that can be inserted in a tee or an elbow in the process piping. As the measuring element corrodes, the cross-sectional area reduces and the electrical resistance increases. The thickness of the measuring element is directly proportional to a corrosion dial reading. The difference in dial readings is plotted over a period of time and from these data, corrosion rate can be determined. Probes are available in a number of different metals for different temperature ranges and corrosion conditions. In another variation, three electrode probes are used. The corrosion rate is determined by measuring electrical current flow between the test and auxiliary electrodes. That current either cathodically protects or anodically accelerates the corrosion rate of the test electrode, depending upon the flow. The current is measured on a microammeter that has been converted to read directly the corrosion rate in mils (1 mil = 0.001 inch = 25.4 micrometers) per year of the test electrode.

In another instrumental approach, a hydrogen test probe operates on the principle that hydrogen will diffuse through the thin wall of a test probe and set up a pressure within the tube. The rate at which the pressure increases is measured by a pressure gage. The rate at which hydrogen is penetrating per unit area can then be determined, using the exposed surface area and the internal volume of the probe. Beyond a certain rate, severe hydrogen damage can be anticipated.

Measurement of wall thickness can be determined using ultrasonic nondestructive testing methodology. See also **Thickness Measurement and Gaging Systems**. This method can be used to determine wall thinning, pitting, erosion, and flaws in metals, plastics, and various rubbers and polymers. Some disadvantages of the method include the need to take many readings over a period of time to determine corrosion rate and the fact that high-temperature measurements tend to be inaccurate.

Infrared thermographic techniques can be used to identify hot spots on process equipment. The camera works on the theory that the hotter the object, the higher the frequency of radiation. For off-line corrosion monitoring, borescopes for inspecting tubes, pumps, compressors, and other equipment may be used. Spot chemical testing can indicate the presence of alloy constituents of unknown materials. Television camera and holographic techniques also have been used. The monitoring of pH is an invaluable indicator of possible corrosion problems, particularly in cooling water systems. Monitoring is usually done continuously because pH shifts can take place rapidly in many systems, particularly as a result of a process leak.

Probably the weight loss coupon approach is one of the most reliable methods and is widely used. The accuracy of the data is highly dependent on good techniques and on the statistical significance of the tests. The engineering quality data produced require the efforts of many people over a period of several weeks or months, which makes this information quite costly. However, it is the technique of first choice of many processors.

CORROSION EMBRITTLEMENT. The or loss of ductility of metals due to corrosion, usually as a result of intergranular embrittlement attack, which may not readily be visible.

CORROSION FATIGUE. The condition caused by the combined action of corrosion and repeated stresses. Both factors may result in damage to and failure of metals, but when acting in concert their combined action usually accelerates the deterioration.

CORROSION INHIBITION. See **Autodeposition**; **Conversion Coatings**; **Paints**; and **Finish Removers** and **Petroleum**.

CORSITE. An orbicular diorite resulting from the segregation, in rounded concentric forms, of ferro-magnesian minerals. It derives its name from its occurrence on the Island of Corsica, and is also sometimes called Napoleonite.

CORTEX. This is the outer portion of a stem or root, bounded externally by the epidermis, and internally by the cells of the pericycle. It is composed mostly of cells that are very little differentiated. Usually these are rather large, thin-walled parenchyma cells. The outer cortical cells often acquire irregularly thickened cell walls. These are the collenchyma cells. Some of the outer cortex cells may contain chloroplasts and carry on photosynthesis.

In zoology, a superficial layer of an organ. Included are such organs as the kidney, the adrenal gland, the ovary, the thymus and portions of the brain. Among these examples the cerebral cortex of the brain is the most familiar. The term designates no common characteristic of origin or structure, but only the existence of a distinctive layer at the surface of the organ involved.

CORTICOSTEROIDS. See **Adrenal Glands**; **Hormones**; and **Steroids**.

CORTICOSTERONE. See **Steroids**.

CORTI (Organ of). A center of nerve terminals located in the inner ear, adjacent to the basilar membrane. See also **Hearing and the Ear**.

CORTISONE. See **Steroids**.

CORUNDUM. The mineral corundum, Al_2O_3, aluminum oxide, occurs as well-developed hexagonal crystals, which may display prismatic, rhombohedral, pyramidal or tabular habits. The larger crystals are often rounded or barrel shaped. Corundum shows both basal and rhombohedral partings; the fracture is conchoidal; hardness, 9; specific gravity, 4.0–4.1; luster, vitreous to adamantine, may be pearly on base; transparent to translucent. Common corundum is gray, grayish-blue or brown, but may be red, yellow or whitish; it is sometimes called adamantine spar. Transparent corundum may be colorless or of various tints. The highly prized ruby is deep red; the sapphire, blue. Transparent yellow corundum is known as oriental topaz; if violet, oriental amethyst; if green, oriental emerald.

Emery is a mixture of granular corundum of dark color, magnetite and hematite, sometimes with spinel. Quartz may be present. For a long time emery was supposed to be an ore of iron. Until the introduction of artificial abrasives, emery was much used for such purposes.

Corundum is found as an accessory mineral in the crystalline rocks such as crystalline limestone and dolomites, gneisses, schists as well as in the igneous rock types granite and syenite. Corundum syenites are found in Canada, especially in the Province of Ontario. Rubies have long been mined in Upper Burma; both rubies and sapphires are found near Bangkok, Thailand. Numerous localities in India furnish gem stones of high quality.

In the United States, common corundum is found in New York, New Jersey, Pennsylvania, Virginia, North Carolina, South Carolina and Georgia; sapphires of gem quality near Helena, Montana, associated with alluvial gold in the Missouri River. From the crystalline limestones and schists of the islands of Naxos and Samos in the Grecian archipelago most of the emery of commerce comes. Other deposits are near Ephesus in the Middle East, and in the town of Chester in Massachusetts. The word corundum comes from the Hindu, kurand; emery is derived from the Greek name for this substance.

See also **Bauxite**.

CORVUS (the raven or crow). A small constellation containing no particularly bright or interesting stars. This group of stars has long been a friend to lovers of the sea because of its resemblance to the "fore and aft" sail of a cutter. For this reason, the constellation is frequently referred to by sailors as "the cutter's mainsail." On a clear, moonless night, the resemblance to the sail is very remarkable, with even the "step" of the mast and a small "pennant" flying from the gaff being discernible. (See map accompanying entry on **Constellations**.)

CORYDALIS *(Insecta, Neuroptera)*. A large gray insect with four membranous wings and, in the male sex, very long slender jaws. The adult of the hellgrammite. Also called dobson fly.

In botany, the term *Corydalis* is applied to a genus of plants occurring in the north temperate regions and in South Africa, which are sometimes found in cultivation. All are herbs with small, somewhat irregular flowers.

COSET. If H is a subgroup of the group G, a set of elements of the form ah, where a is in G and h runs through H is called a (left) coset of H in G and a set of the form ha is a right coset. The number of such cosets is called the *index* of H in G.

See also **Group**.

COSINE EMISSION LAW. A law relating to the emission of radiation in different directions from a radiating surface. If a small, white-hot metal plate is viewed from a great distance, its apparent candle power, measured by a photometer is greatest when it is perpendicular to the line of sight, and reduces to practically zero when it is turned edgewise. If the observer now moves nearer, he finds that this change is due to the smaller angle subtended by the surface, that is, the smaller cross section of the beam proceeding from it in his direction; the apparent brightness of the surface is the same however it is turned. To apply this, let the radiating surface, of area a, be emitting a luminous flux L (lumens) in the normal direction (see Fig. 1), and, in any other direction making an angle θ with the normal, the smaller quantity L'. Then since the apparent brightness is unchanged, $L'/a' = L/a$. This gives $L'/L = a'/a$. But $a'/a = \cos\theta$, hence $L' = \cos\theta$; which means that the energy emitted in any direction is proportional to the cosine of the angle that direction makes with the normal. This is the "cosine emission law" of Lambert. It applies to thermal radiation as well as to light, and to diffusely reflected as well as directly emitted radiation. The law is true only for a perfectly diffusing surface, strictly, for a black body, but it is a good approximation to the behavior of many surfaces.

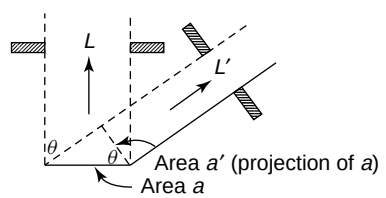

Fig. 1. Illustration of cosine emission law.

COSMIC HOT INTERSTELLAR PLASMA SPECTROMETER (CHIPS) MISSION. See **Explorers Program**; and **Space Science Missions: Universe**.

COSMIC RAYS. Generally, cosmic rays are divided into two classes: (1) primary, and (2) secondary. The first rays, for the most part, are

energetic charged particles of extraterrestrial origin, while the latter are the products resulting from collisions of the primary cosmic rays with atoms of the earth's atmosphere.

Primary Radiation. This is characterized by at least four qualities: (1) the primary intensity is essentially constant in time; (2) isotropic in space; (3) anomalous in composition; and (4) it contains very energetic particles. Measurements indicate that with the exceptions of the local perturbations, described later under solar effects, the primary cosmic ray intensity exhibits less than 1% variation in time. Measurements of radioactivity produced in meteors by cosmic rays show that the intensity has not appreciably changed in the last several million years.

Isotropy simply means that there is no direction or particular directions in the cosmos from which the bulk of cosmic radiation emanates, including the direction of the sun. Since there are magnetic fields of varying magnitude and direction throughout interstellar space that deflect charged particles, the isotropic nature of the primary intensity is not surprising. It could be concluded that because of collisions of the cosmic rays with these fields, the primary particles lose their "memory" so to speak of the directions to their source. Magnetic fields also act in other ways. For example, the earth's field effectively prevents particles of less than 10^8 eV energy from reaching the earth at all (1 eV $= 1.6 \times 10^{-19}$ joule). Moreover, there is indication that cosmic rays between 10^{14} and 10^{18} eV may be very slightly guided along the field lines of the local spiral arm of our galaxy. It should be observed that the diameter of the orbit of a proton of 10^{18} eV moving in the galactic magnetic field would be comparable with the thickness of the galactic disk, so that above 10^{18} eV such guidance would not be impossible.

The total number of primary cosmic rays striking the earth's atmosphere is roughly 1 cm^{-2} sec^{-1}. These particles are mostly protons, but decreasing proportions of heavier atomic nuclei are present, ranging from helium (15% of the proton intensity for the same momentum-to-charge ratio) all the way to iron. Although there are many interesting features of the primary composition, one of the most notable is that the abundance of the elements in cosmic rays is very different from the chemical composition of the sun. Not only are cosmic rays relatively rich in heavy nuclei, but there is roughly one million times as much lithium, beryllium, and boron in cosmic rays as in the sun. These light elements presumably arise from collisions of heavy nuclei with interstellar matter. Such considerations determine a value of a few grams per square centimeter for the average amount of matter traversed by cosmic rays before reaching the earth. This, in turn, gives a mean lifetime of cosmic rays in the galaxy (density $\sim 10^{-26}$ grams per cubic centimeter) on the order of 10^8 years or $\sim 10^6$ years in the spiral arms.

The spectrum of cosmic ray energies between 10^{14} and 10^{19} eV is a power law relation given by $N(>E) = 3 \times 10^{-10} E^{-(1.7+0.1 \log_{10} E)}$ (cm^2 sec steradian)$^{-1}$, where E is the energy in 10^{15} eV. this spectrum should not be extrapolated beyond the indicated upper limit since some experiments indicate a possible change in the slope beyond this point. The maximum particle energies that have been detected are well in excess of 1 joule. These are truly phenomenal energies, equivalent to taking all of the kinetic energy of an apple dropped a distance of several meters and giving it to just one proton of the apple's atoms. Not only are some cosmic rays individually energetic, but because of their high spatial density, cosmic rays represent a large fraction of the total energy associated with astrophysical phenomena. The energy density of cosmic rays, optical photons, interstellar magnetic fields, and the turbulent motions of interstellar matter are each about equal to 1 eV/cm^3.

Origin. Since their discovery by Hess in 1911, the problem of the origin of cosmic rays has not been fully solved. The major difficulty has been that of finding a satisfactory mechanism whereby charged particles can be accelerated to the very high energies described. The earth's sun is wholly inadequate in this respect; the sun it appears cannot be considered as the sole source of cosmic rays.

Speculation considers the sources to be violently active celestial objects — exploding galaxies and exploding stars or supernovae. Supernovae are known to be rich in heavy elements. These exploding phenomena involve huge amounts of energy. This is inferred from the presence of synchrotron radiation (the emission of electromagnetic waves by electrons moving in magnetic fields) which implies in some instances electron energies as high as 10^{13} eV. These electrons are most likely the decay products of mu-mesons which are again decay products of charged pi-mesons. The pi-mesons are created in nuclear interactions, thereby suggesting the presence of very energetic nuclei, some of which could escape from the magnetic fields of the supernovae to become cosmic rays. There are possibilities of verifying such a model, for neutral pi-mesons should also be produced in the nuclear interactions. These mesons decay into gamma rays that travel in straight lines unaffected by magnetic fields. Thus, experiments to detect high-energy gamma rays coming from supernovae and radio-galaxies will assist in the cosmic-ray origin problem.

High-energy photons have been observed in the primary cosmic rays. Gamma and x-rays produced by interaction of primary particles with interstellar matter and optical photons (inverse Compton scattering) give information on the distribution and composition of matter in our galaxy. Several point sources of x-rays have been discovered, one of which is in the Crab Nebula. Processes whereby these x-rays are created are being investigated. All high-energy interactions lead ultimately to the production of neutrinos. So-called neutrino astronomy would be a useful tool for the study of astrophysical phenomena.

In mid-1967, an intense burst of gamma rays was recorded by several Vela satellites (monitors for Nuclear Test Ban Treaty). Although the information was not publicly released for some years, careful examination of this and later similar events showed that the radiation did not come from any nuclear devices, or, in fact, from within our solar system. Since that time, about five similar events have been detected each year. The events are characterized by an initial short pulse of gamma rays, ranging from 0.1 to 4 seconds, followed by one or several pulses, with the entire burst over within about 1 minute.

Unlike the radiation with energy of 50 MeV (million electron volts) studied by gamma ray astronomers, the more recently noted bursts occur between 0.1 and 1.2 MeV, with no clear distinction at the lower end of the energy range between gamma and x-rays. The intensity of the bursts leaves little doubt that the signal may simply be a fluctuation in the intensity of background noise, sometimes encountered when discrete sources of high-energy gamma rays are analyzed.

As of the end of 1973, nearly 25 such bursts had been cataloged by scientists at the Los Alamos Scientific Laboratory. There is ambiguity concerning the location of most of the bursts, but with only limited exceptions, it is evident that the bursts do not come from the earth, the sun, the planets, or the closest stars. Supernovas in our galaxy do not seem to occur with sufficient frequency to account for the bursts. Prior thinking led to the conclusion that well-known astronomical objects were not expected to produce the type of gamma ray bursts that have been observed — the recently observed bursts are less energetic, longer in duration, and multiple rather than singular.

Since the discovery of the unexplained gamma bursts was announced in June 1973, numerous theories have been proposed, including a modified theory for sources in extragalactic supernovas and an unusual concept suggesting that the gamma rays may come from the breakup of relativistic "beebees" within the solar system. These concepts are described in reference listed (Metz).

Interesting work on the difference between the energy spectra of iron and other cosmic rays has been conducted at the Goddard Space Flight Center and is reported, in part, in reference listed (Ramaty, R., et al.). Two source mechanisms have been proposed. One mechanism, possibly acceleration at neutron star surfaces, produces the iron; another is responsible for the rest of the primary nuclei. Within this model, observations of high-energy cosmic rays could determine whether secondary nuclei are produced in the sources or in the interstellar medium.

Solar Effects. Although the sun appears to have little effect on the high-energy cosmic-ray flux, it strongly influences the low-energy flux during the occurrence of solar flares. At such periods of solar activity, protons may be emitted by the sun, with kinetic energies of nearly 10^{11} eV. The accompanying increase in the sea-level cosmic-ray intensity can be as much as 50 times larger than the normal value of about 1.0 cm^{-2} min^{-1}.

The earth is surrounded by electron ring currents circulating in the earth's magnetic field. These ring currents (Van Allen belts) contain electrons with energies ranging from 10^3 to 10^5 eV. Occasionally, the sun emits an ionized gas, which moves outward with a velocity of 10^3 kilometers/second. These particles do not have enough energy to penetrate the earth's magnetic field, but they do modify the field, thereby releasing electrons trapped in the Van Allen belts. When the electrons strike the atmosphere, the resultant ionization produces auroras. The magnetic fields associated with the ionized gas also prevent low-energy

galactic cosmic rays from reaching the earth. The accompanying decreases in the sea-level cosmic-ray intensity are known as Forbush decreases. Since these fluctuations in intensity are related to solar activity, their occurrence is periodic and associated with the 11-year solar sunspot cycle.

Secondary Radiation. If it were not for the secondary cosmic rays, high-energy primaries would not have been discovered. Consider a particle detector of an area of 1 cm^2 and an aperture of 1 steradian. With such a detector, one would have to wait nearly 10^{10} years (the lifetime of the universe) before registering the passage of a 1-joule particle. However, the detection frequency is enormously enhanced by the earth's atmosphere.

The layer of air above the earth represents about 13 collision mean free paths for an incident proton. After the inevitable interaction of a primary particle with some atom high in the atmosphere, the nuclear debris so produced undergoes successive interactions with air atoms further down in the atmosphere. In each collision, pi-mesons are created with decay into mu-mesons and gamma rays. Owing to their large Lorentz factors commensurate with their high energies, the mu-mesons continue on down to sea level before decaying. The gamma rays, on the other hand, produce electron-positron pairs, which, in turn, radiate more gamma rays. The huge number of electrons created in this way is called an extensive air shower (EAS). After reaching a maximum at an atmospheric depth dependent on the energy of the primary particle, the EAS slowly decays by ionization losses. Even so, energetic primaries can give rise to EAS that contain billions of electrons at sea level. The total number of EAS particles reaching sea level is nearly proportional to the primary energy, the relation being roughly 10^9 to 10^{10} primary eV per secondary electron.

As they cascade down through the atmosphere, the electrons are scattered by air atoms so that, upon reaching sea level, the EAS electrons and positrons are distributed over a large area. The density distribution of these secondaries is peaked around the shower axis (the direction of motion of the primary particle) and decreases monotonically with distance in a plane perpendicular to the shower axis. For example, a 1-joule primary can create detectable numbers of electrons per square meter, even at distances of 1 kilometer from the shower axis. Thus, a small number of detectors spread out in a plane (1) can detect EAS produced by energetic primaries; (2) can give information concerning the primary energy from knowledge of the secondary electron density distribution; and (3) can be used to determine the incidence angle of the primary particle. The last measurement involves timing the arrival of the shower front (the nearly plane surface containing the majority of the secondaries and propagating along the shower axis with the velocity of light) at several distances from the shower axis. By spreading a dozen or so detectors over an area of 10^6 square meters, several showers representing primaries of 1 joule or more can be detected per year.

In order to extend the detectable upper limit of primary cosmic-ray energies, other techniques are in use which effectively increase the sensitive area of the individual detectors. These methods involve the detection of the atmospheric fluorescence produced isotropically (hence detectable over a wider area than the electrons themselves) by the secondary electrons as they pass through the atmosphere.

Among the many uses of the secondary radiation has been the discovery of new particles, notably the positron and the various mesons, and the study of their interactions with matter. In addition, some of the interactions provide remarkable clocks for finding the age of many terrestrial features. For example, the collisions of secondary neutrons with atmospheric nitrogen produce ^{14}C which combines with oxygen to form radioactive carbon dioxide, thus facilitating the familiar technique of radiocarbon dating developed by Libby.

COSMIC WATER. Once believed by science to be the substance that distinguished the earth from the rest of the universe, it is now understood that water is ubiquitous in the cosmos — not only as ice and vapor, but also as liquid. Sophisticated scientific instruments can detect cosmic water on the basis of the light, or other electromagnetic, waves that it absorbs and emits (1). Unlike the legendary "waters of chaos" that gave rise to the material world, water's component hydrogen and oxygen atoms owe their existence to the Big Bang and to the stars, respectively.

Hydrogen and Oxygen

Hydrogen is both the simplest and the most abundant atom in the universe. It represents about 75% of the atomic mass in the cosmos. The word *hydrogen* literally means "water-forming" according to the Greek language from which it is derived. Hydrogen atoms are generally traced back to the so-called Big Bang, when a tremendous amount of energy was released and subsequently expanded into what we call our universe. As the newborn universe began to cool, subatomic and atomic particles (e.g., quarks, protons, electrons) were initially created and later drawn together by a number of fundamental forces to form atoms. Possessing one proton and one electron, hydrogen is believed to have been the first atom created. As more hydrogen atoms were created in the early universe, they coalesced into dense gas clouds that contained much of the conventional matter.

Oxygen is the third most abundant atom in the cosmos — behind hydrogen and helium. Because helium is a very inert (nonreactive) atom, water is sometimes described as an interaction between the two most abundant "reactive" atoms in the cosmos. Unlike hydrogen, the origins of the oxygen atom are rooted in dying stars rather than in the Big Bang. As stars near the end of their stellar life, they begin to cool and to switch from hydrogen to helium as a source for nuclear fusion. The cooling stars then enter a phase where they become increasingly dense as intense gravitational energy compresses them into an extremely unstable state that may explode during the final stages of compression. This explosion or *supernova* releases the outer layer of the star, which contains many common heavier atoms (e.g., oxygen, carbon), into space as interstellar clouds. Dust grains comprising these clouds are composed of both silicate (oxygen-rich) and carbonaceous (carbon-rich) minerals that are available to react with hydrogen.

Interstellar Space

In the interstellar realms of galaxies, water exists predominantly as ice — adhering to the tiny particles that comprise the ubiquitous dust and

gas clouds. Water is the primary molecular ice attached to these particles, although methane, carbon monoxide, and water–ammonia mixtures may also be present depending on physical conditions in the gas clouds. Water ice in the 10 K temperatures and vacuum conditions of interstellar space is what physical chemists refer to as *amorphous ice* or *glassy water*; it is relatively unstructured compared to the highly crystalline ices that are formed at higher temperatures (e.g., those characteristic of the earth's surface and atmosphere). Amorphous ice is so unstructured that it can flow, not unlike a viscous version of liquid water. Some astrophysicists posit that the simple organic molecules responsible for biological life may have been created in this strange ice. As interstellar temperatures rise above 150 K (as often occurs near stars), amorphous ice irreversibly transits to more familiar crystalline ice. The various phases and molecular structures of water as a function of temperature are shown in Table 1.

Although water's component atoms are plentiful in interstellar dust and gas clouds, creation of molecular water requires either converting O and OH species directly to water ice on the surfaces of dust grains or producing water vapor via heat energy — usually in the form of stellar radiation. The latter process requires that water vapor adhere to dust grains, where the newly formed water molecule is protected from the same ionizing radiation that created it. Scientists currently believe that stars facilitate the creation of water vapor and also that water vapor assists in the birthing of stars. Stars are being born and are dying on an ongoing basis, such that star birthing regions (e.g., the Orion Cloud Complex of the Milky Way Galaxy) generate up to 20% of a galaxy's luminosity as gas and dust clouds are gravitationally compressed into newborn stars. Recent data indicate that these cloud complexes contain an extremely high concentration of water vapor, which has been estimated of the order of 1 part in 2000. The superabundance of water in stellar nurseries (about 20 times greater than that in similar interstellar clouds) may permit the gas and dust to cool sufficiently so that condensation can proceed and stars are eventually formed.

As hot winds (in the form of shock waves) are sent out during stellar birthing, the cloud must be cooled — initially by molecular hydrogen and subsequently by water and other simple gases. Water vapor is created during the interstellar cloud shocks as oxygen reacts explosively with hydrogen, causing the water vapor concentration to increase substantially during star birthing. Scientists have theorized one of two eventual fates for water created in star birthing. One is that the intense heat of the fledgling star rapidly dissociates water into its component atoms. The other is that the water is deposited on dust grains that later form the star's planetoids. The origin of earthly water is usually attributed to either this second process or the impact of large comets, which are believed to have been more prevalent during the earth's early history.

Stars

Two of the brightest supergiants in our galaxy, Betelgeuse and Antares, have water in their *photospheres* , which constitutes the visible portion of a star. A star's photosphere is where its gases transit from opaque to transparent, permitting us to see the stars that are located closest to the earth. This stellar water is actually present within the star itself, not simply as a component of the surrounding dust and gas cloud from which the star was birthed. Aging supergiant stars release massive amounts of water as they die; however, the exact source and role of this water are not yet known.

In addition to cool stars, water has been discovered in the photosphere of at least one hot or *main sequence* star — the Sun. Water cannot exist on the surface of the Sun, where temperatures of 6000 K dissociate the water molecule into its component hydrogen and oxygen atoms. Water can exist in the dark centers of sunspots, where temperatures are less than 3500 K. Sunspots are relatively calm solar regions where strong magnetic fields filter out the energy emanating from the intense interior, rendering them both the coolest and darkest regions of the Sun. Water is a major player in determining a star's *radiative opacity* , which describes the extent to which light escapes from stars into interstellar space. In this role, water impedes the outward flow of radiation from stars by absorbing energy within certain wavelengths and, thus, renders the star more opaque than it would otherwise appear.

Comets and Meteors

Comets are one of the few interstellar objects that are commonly associated with water, predominantly as ice. Comets are composed primarily of water ice that incorporates many of the other simple molecules in interstellar dust and gas clouds (e.g., carbon monoxide, methane, ammonia). Comets are most easily recognized by their unmistakable tails, which can extend millions to hundreds of millions of kilometers behind the icy body of the comet. The tail consists of dust and ionized particles (mostly water ice) that are always transported away from the Sun by the *solar wind*, which is an ionized stream of particles consisting predominantly of protons and electrons. The ionization of water ices is the primary mechanism influencing the properties of a comet's tail, including the steam jets that release tons of water vapor per second from the comet. It is now believed that these steam jets result from solar-induced changes in ice's molecular geometry (e.g., a transition from the amorphous to crystalline structure). Large comets are generally accepted as a source of planetary water, but controversy surrounds the hypothesis that many small comets hitting the planet's upper atmosphere also contribute significantly to the volume of water on the earth.

The first liquid water in the solar system, it was projected, made its appearance on meteors just 20 million years after our Sun and its debris emerged from the interstellar dust and gas cloud. Although liquid water is rarely present on the surface of meteors today, the chemical interaction of water with primitive rocks produced carbonate minerals, suggesting that the chemical processes of water evaporation and condensation were among the earliest in the solar system. Recently, a small meteorite found in southwestern North America contained actual liquid water within its salt crystals, which were believed to have been created from the original interstellar cloud that gave rise to the solar system.

Planetoids

Most planet-sized bodies in our solar system (and probably in others) are now known or suspected to contain water in some form. A number of recent missions have revealed a Martian landscape that almost certainly indicates the large-scale flow of liquid water. The surface features of Mars (e.g., flood plains, river beds, mud deposits) suggest the recent presence of liquid water and also the mineralogy of Martian rocks could have resulted only from aqueous processes. Moreover, it has been hypothesized that Mars may have also once possessed surface oceans. The Jovian moon, Europa, is another of the solar system planetoids that probably contains liquid water located tens of kilometers beneath its icy surface. The liquid water underlying Europa's surface ice is believed to be an ocean containing saltwater that may be similar in composition to the seawater of the earth's oceans. Unlike the earth, the heat required to maintain water in a liquid phase on Europa is believed to originate from an internal source such as volcanic activity rather than from the heat of the Sun. See also **Jupiter**; and **Marrs**.

Data collected from the Infrared Space Observatory indicate the presence of water in the upper atmospheres of our solar system's gas giant planets and on one of Saturn's moons. The source of water in these planet's atmospheres is attributed to comets or to water-containing interplanetary

TABLE 1. REPRESENTATIVE TEMPERATURE RANGES AND COSMIC LOCATIONS FOR THE THREE PHASES OF WATER

Location	Temperature, K[a]	Phase	Comments
Stellar surfaces	4000 to 50,000	None	Water molecules do not exist. Only hydrogen and oxygen atoms or plasma.
Stellar/planetoid surfaces	3500	Vapor	Water exists at the surface of cool stars and in cooler regions of some hot stars.
Some planetoids	273 to 373 (at 1 atmosphere)	Liquid	Few places in the cosmos possess the requisite temperatures and pressures.
Interplanetary/interstellar space	>100	Solid (crystalline)	Crystalline ices possess both a cubic and a more common hexagonal structure.
Interstellar space	10 to 150	Solid (amorphous)	The depths of interstellar space are cold enough to produce glassy water.

[a] These temperatures, which are measured on the Kelvin scale, are only approximate and vary depending on environmental conditions (e.g., pressure, rate of cooling or heating)

dust. Based on recently developed techniques for measuring a suite of stellar characteristics (e.g., orbital velocity, position, brightness), the search for planets has been extended beyond our solar system to other star systems in the galaxy. Various planets have been identified orbiting stars in the constellations of Leo, Pegasus, Virgo, and Ursa Major that probably possess surface temperatures ranging from slightly less than 100 °C down to −100 °C. Planets or moons characterized by this temperature range could possess water in solid, gaseous, and liquid phases.

COSMOLOGY. The study of the origin, current state, and future of our Universe. This field has been revolutionized by many discoveries made during the past century. These observations have shown that the Universe is vastly larger than the cosmos of the ancient Greeks, who put the Earth in the center of a planetary system that filled most of the Universe. Until a few hundred years ago, the Solar System and the Universe were equivalent in the minds of scientists, so the discovery that the Earth is not the center of the Solar System was an important step in the development of cosmology. But it was only in the 20th century that the Sun was found to be on the outskirts of the Milky Way galaxy, and it was found that the Milky Way was only one of billions of galaxies.

Early History

When Copernicus proposed a heliocentric model to explain the motions of the planets, it was neither simpler nor more accurate than the geocentric Ptolemaic model of Claudius Ptolemy that was then accepted. But Galileo Galilei's observations of the moon of Jupiter using the newly invented telescope showed that astronomical bodies could orbit around objects other than the Earth, and his observations of the phases of Venus showed that this planet circled the Sun. See also Telescope. Tycho Brahe proposed a model in which all the planets except the Earth circled the Sun, but the Sun and the Moon orbited the Earth, which was stationary at the center of the Universe. Tycho knew that if the Earth orbited the Sun, then all the stars should appear to wiggle back and forth with a period of one year. Tycho was not able to measure this annual parallax, and concluded that the Earth must not be moving. But Tycho's accurate measurements of planetary positions were used by Johannes Kepler to devise a heliocentric model of the Solar System that was much more accurate than the Ptolemaic model. Isaac Newton used Kepler's Laws to derive his theory of gravity, which gave the heliocentric model a very sound theoretical basis. But the annual motion of the stars sought by Tycho was not seen for more than 200 years because the stars are very far away so the parallax is very small. Bradley discovered the aberration of starlight, which is 30 times larger than the largest parallax, only one century after Tycho, and this observation firmly established that the Earth was moving around the Sun.

Galaxies

Once astronomers knew that stars were many light years away from the Sun, measurements were made to map out the system of stars and locate the Solar System within the Galaxy. Herschel counted stars and produced a map of the Milky Way which was flattened like a disk with the Sun close to the center. This disk of stars was about 10,000 light years across. But Harlow Shapley studied globular clusters of stars which appear to be in a spherical distribution that is centered on a position about 30,000 light years away in the direction of the constellation Sagittarius. Shapley was able to determine the distance to globular clusters by using the properties of certain types of pulsating stars. Observations of the Milky Way in the infrared and radio bands with wavelengths longer than visible light show that this position toward Sagittarius is indeed the center of the Milky Way galaxy, and that the Sun is located far from the center. Figure 1 shows an infrared view of the Milky Way with Sagittarius in the center. This image of the Milky Way looks very much like images of edge-on spiral galaxies like NGC 891 or NGC 4565. There are billions of faint galaxies visible on the sky, so cosmologists have learned that: the Earth is not at the center of the Solar System, the Sun is not at the center of the Milky Way, and the Milky Way is but one of billions of galaxies. This is the culmination of the philosophical revolution started by Copernicus. The Earth is not in a special place in the Universe.

The existence of other galaxies like the Milky Way was only established during the early 20th century. There are many faint fuzzy patches of light on the sky, known as nebulae. When examined with a spectrograph, spiral-shaped objects like the Andromeda nebula showed the dark lines characteristic of stars. But the position of these dark lines in the spectrum was most often shifted to the red. This Doppler shift to the red, or a redshift, indicates that these nebulae are moving away from the Solar System. Edwin Hubble tried to find a relationship between these galaxy redshifts and the distances to the galaxies. Hubble obtained the data points shown in Figure 2 see also doppler Effect; Galaxy.

Hubble's Law

Hubble found that the relationship between the radial velocity and the distance of a galaxy was described by a linear law: $v = KD$. Now we call this the Hubble law, and use H for Hubble's constant. In most cosmological models, Hubble's "constant" actually varies with time, so we write $v = H_o D$, where the subscript "naught" means the value at the current time. If all galaxies followed Hubble's Law exactly, all the data points would fall on the diagonal line. Clearly the data available to Hubble were not in exact agreement with his linear law.

Looking at Fig. 2, we see that Hubble derived $H_o = 500$ km/sec/Mpc. One Megaparsec is $3.08{*}10^{19}$ km, so this value can be simplified to give $H_o = (500 \text{ km/sec})/(3.08{*}10^{19} \text{ km}) = 1/(6.16{*}10^{16} \text{ sec}) = 1/(2 \text{ billion years})$. If all objects follow $v = H_o D$ now, and the velocities do not change, then at a time $1/H_o$ ago all the distances would be zero. Thus Hubble's data implied a Universe only 2 billion years old, which is much too short. This was caused by a calibration error in Hubble's distances, which were much too small. Both the large scatter and the distance errors have been reduced by modern observations. The best objects known for testing the Hubble Law are Type Ia supernovae, which are both extremely bright, so they can be seen at great distance, and also well calibrated using a kind of pulsating star known as a Cepheid variable. The Hubble Space Telescope has been used to measure Cepheid variables in many nearby

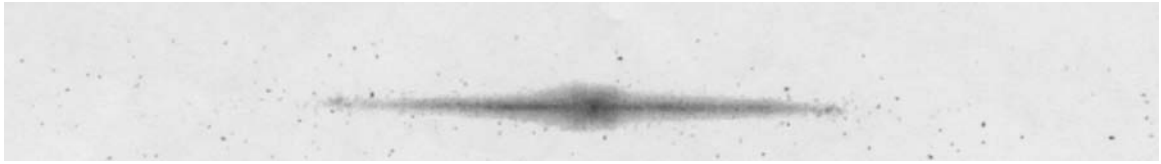

Fig. 1. Infrared (IR) View of the Milky Way. This is a panorama that goes all the way around the sky, constructed from data from the Diffuse Infrared Background Experiment (DIRBE) on the Cosmic Background Explorer (COBE).

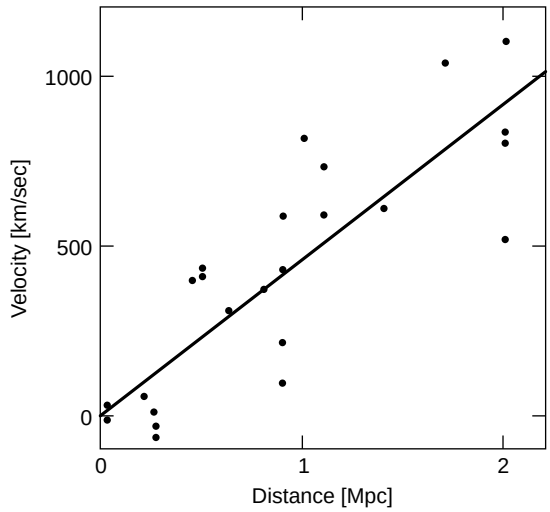

Fig. 2. The radial velocity of galaxies, measured in kilometers per second using Doppler shift, versus their distance in Megaparsecs. This is Hubble's data from 1929.

galaxies, and this data has greatly reduced the errors in Hubble's Law. See also **Hubble Space Telescope (HST)**. Figure 3 shows recent data on Type Ia supernovae. Note that the velocities cover a range 30 times greater than Hubble's 1929 velocities, and the distances cover a range 250 times greater than Hubble's 1929 distances. As a result, Hubble's constant is reduced to $H_o = 65$ km/sec/Mpc, and the "age of the Universe" given by $1/H_o$ is 15 billion years, in good agreement with the ages of the oldest stars.

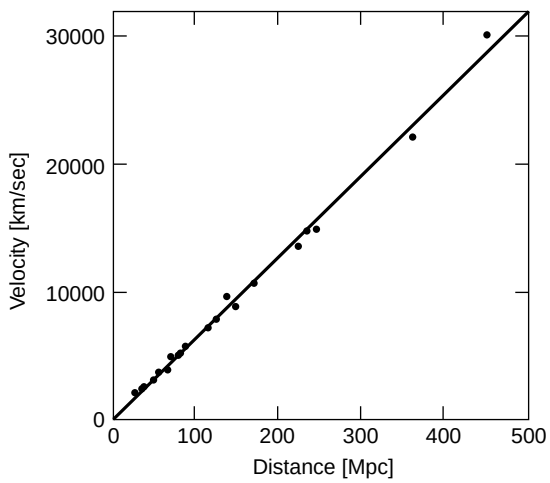

Fig. 3. Radial velocity versus distance in Megaparsecs for Type Ia supernovae, based on data taken in the 1990's.

Models of the Universe

Because the velocity is proportional to the distance, the percentage growth in the distance between any pair of objects following the Hubble law during a given time interval is independent of which pair of objects is considered. This means we can write the distance, given any pair of objects, as $D(t) = a(t)^* D_o$, where $a(t)$ is the scale factor for the Universe, the same for any pair of objects, and D_o is the current distance between the pair. The scale factor $a(t)$ is a function of time, and different cosmological models predict different behaviors for $a(t)$. Because the radial velocities are positive (redshifts instead of blueshifts) $a(t)$ must be an increasing function of time. By the definition of $a(t)$, $a(t_o) = 1$, and $a(t)$ was less than 1 in the past. If there were a time when $a(t)$ were zero, then that time would have corresponded to the origin of the Universe. George Gamow proposed a model in which $a(t)$ started out from zero, and thus the Universe was very dense in the first few minutes. Fred Hoyle proposed a model in which the doubling time for $a(t)$ was constant. Thus, taking Hubble's original value of $H_o = 500$ km/sec/Mpc, Hoyle predicted $a(t)$ was 0.5 at a time 1.4 billion years ago, 0.25 at 2.8 billion years ago, 0.125 at 4.2 billions years ago, etc. This law predicts that $a(t)$ never reaches zero, so there is no time at which the Universe was created. The rapid growth of $a(t)$ spreads galaxies so far apart that Hoyle's model would soon be empty. Hoyle prevented this emptying of the Universe by proposing the continuous creation of matter. This is the Steady State model of the Universe, in which the Hubble constant is really a constant, and so is the density of the Universe. In a 1950 radio lecture Hoyle first used the term "Big Bang" to refer to Gamow's model. Note that with the Steady State model the Universe is infinitely old even for a very large value of the Hubble constant, and this was a point in favor of the Steady State when it appeared that the "age of the Universe" given by $1/H_o$ was less than the age of the Earth.

The Hubble law defines a special frame of reference at any point in the Universe. An observer having a large motion with respect to the Hubble flow would measure blueshifts in front and large redshifts behind, instead of the same redshifts proportional to distance in all directions. Thus we can measure our motion relative to the Hubble flow, which is also our motion relative to the observable Universe. A comoving observer is at rest in this special frame of reference. Our Solar System is not quite comoving: we have a velocity of 370 km/sec relative to the observable Universe. The Local Group of galaxies, which includes the Milky Way, appears to be moving at 600 km/sec relative to the observable Universe.

Cosmological Principle

Hubble also measured the number of galaxies in different directions and at different brightness in the sky. He found approximately the same number of faint galaxies in all directions, even though there is a large excess of bright galaxies in the Northern part of the sky. When a distribution is the same in all directions, it is isotropic. And when he looked for galaxies with fluxes brighter than $F/4$ he saw approximately 8 times more galaxies than he counted which were brighter than F. Since a flux 4 times smaller implies a doubled distance, and hence a detection volume that is 8 times larger, this indicated that the Universe is close to homogeneous (having uniform density) on large scales.

The Cosmological Principle states that the Universe is homogeneous and isotropic. This codifies the Copernican principle by stating that all places in the Universe are equivalent, so the Earth cannot be in a special place. Of course the Universe is not really homogeneous and isotropic, because it contains dense regions like galaxies and planets. But the Universe can be statistically homogeneous and isotropic when smoothed on large enough scales. Thus for 100 Mpc regions the Universe is smooth to within several percent.

Background Radiation

The discovery of the microwave background radiation in 1965 by Arno Penzias and Robert W. Wilson provided the best observational data in favor of the cosmological principle. The cosmic microwave background (CMB) radiation is the radiation left over from the origin of the Universe. This radiation looks like the radiation from a blackbody with a temperature of 2.725 K, where 1 K = 1 degree on the absolute Kelvin scale, so 2.725 K is just a few degrees above absolute zero. See also **Absolute Zero**. The temperature is almost the same in all directions except for being 0.123% hotter on one side of the sky and 0.123% colder on the other side of the sky. This particular difference is how one knows that the Solar System is moving at 370 km/sec = 0.123% of the speed of light with respect to the observable Universe. After allowing for the velocity of the Solar System, the remaining temperature fluctuations are less than 100 microK. Thus the Universe is isotropic to one part in 30,000 when looking at the CMB. See Figure 4.

Big Bang Theory

The discovery of the CMB led to the end of the Steady State theory as a viable model of the Universe. The Universe is not now in a state that could produce the CMB and since in the Steady State model the Universe does not evolve, there can be no CMB in the Steady State model. The Universe must have evolved from a hot dense state, cooling and expanding until the present epoch.

Another piece of evidence in favor of the Big Bang Theory (BBT) is the abundance of the light elements, like hydrogen, deuterium (heavy hydrogen), helium, and lithium. As the Universe expands, the photons of the CMB lose energy due to the redshift and the CMB becomes cooler. That means that the CMB temperature was higher in the past. When the Universe

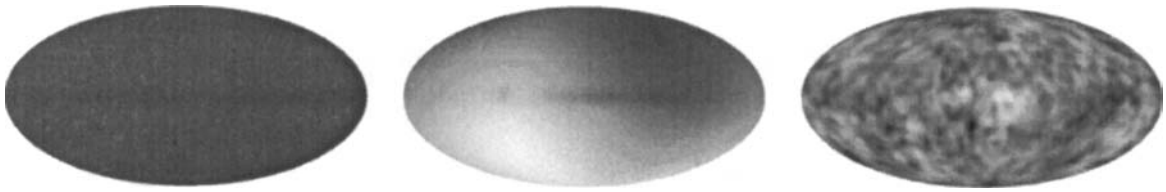

Fig. 4. Negative gray scale images of the CMB temperature, in which hotter regions are darker. Left: the actual temperature is nearly perfectly uniform across the sky. Middle: With the average temperature subtracted and the contrast enhanced by a factor of 400, what is seen is called the dipole anisotropy, with one hot pole and one cold pole. The Solar System is moving at 370 km/sec toward the dark part of the map. Microwave emission from the Milky Way can be seen along the equator of this map, which is known as a Mollweide equal area map in galactic coordinates. Right: With the dipole and Milky Way emission removed, and the contrast enhanced by a factor of 6667, the intrinsic anisotropy of the CMB can be seen. Data from the Differential Microwave Radiometers (DMR) instrument on COBE.

was only a few minutes old, the temperature was high enough to make the light elements by nuclear fusion. The theory of Big Bang Nucleosynthesis predicts that about 1/4 of the mass of the Universe should be helium, which is very close to what is observed. The abundance of deuterium is inversely related to the density of nucleons in the Universe, and the observed value of the deuterium abundance suggests that there is one nucleon for every 4 to 7 cubic meters (approximately 140–350 cubic feet) of space in the Universe. These abundances were determined by reactions occurring during the first three minutes after the origin of the Universe. At this time the temperature of the background radiation was more than 1 billion K, much hotter than the temperature in the center of a star.

About two months after the Big Bang, the reactions between electrons and photons that determine the spectrum of the CMB become slower than the expansion rate of the Universe. Prior to this time, the CMB spectrum was required to be a very good blackbody spectrum. After this time, reactions could change the spectrum of the CMB to a non-blackbody form. But the expansion of the Universe just changes a blackbody into another blackbody with a lower temperature. The actual spectrum of the CMB differs from a blackbody by less than 1 part in 20,000, which places very tight limits on any reactions that would change the spectrum of the CMB. See Figure 5. See also Black Body.

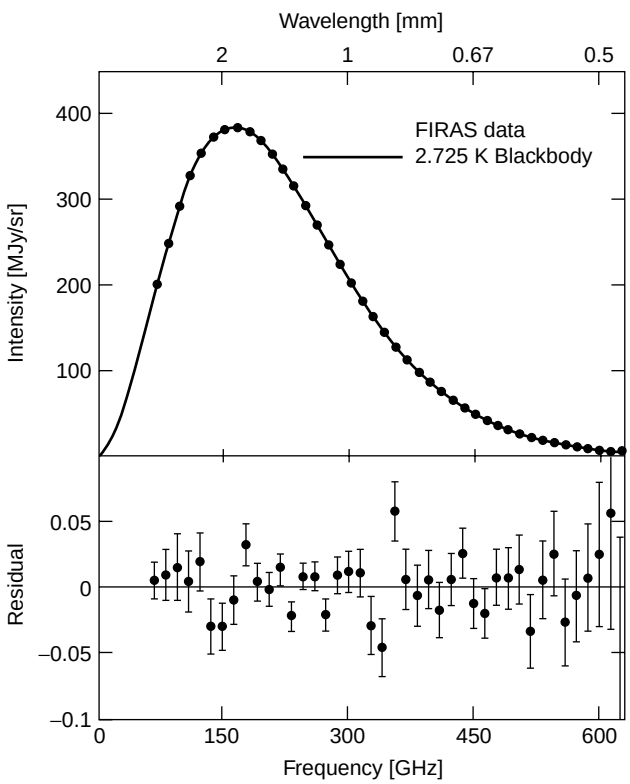

Fig. 5. Spectrum of the CMB measured by the Far Infrared Absolute Spectrophotometer (FIRAS) on COBE. The top panel shows the data with a 2.725 K blackbody curve, while the bottom panel shows the deviations from the blackbody curve with the y-axis expanded by a factor of 1500. One megaJansky (MJy) is 10^{-20} W/m^2/Hz.

There are two mysteries hidden in the initial conditions of the standard hot Big Bang model. One of these mysteries involves the fact that the density of the Universe is fairly close to critical density. The critical density is the density that makes the Hubble velocity at the surface of a spherical region equal to the escape velocity from the mass in the spherical region. If the Universe has a density higher than the critical density, then it should recollapse, just like a rocket ship that is launched with less than the escape velocity will eventually fall back to the ground. Also, the curvature of the Universe depends on its density, with a positive curvature (like a sphere) for densities higher than critical, and negative curvature (like a saddle) for densities less than critical. If the density is exactly critical, then the curvature is zero, like a flat surface. But it is very difficult to launch a rocket with exactly the escape velocity, and it is very difficult to set up the initial conditions for the Universe so it can reach its present large size with a density that is close to the critical density. A density error of only 1 part in 10^{60} at the earliest moments makes a tremendous difference now. How did the density get set to such precision? This is called the flatness-oldness problem since the difficulty is in making an old, nearly flat Universe. See Figure 6.

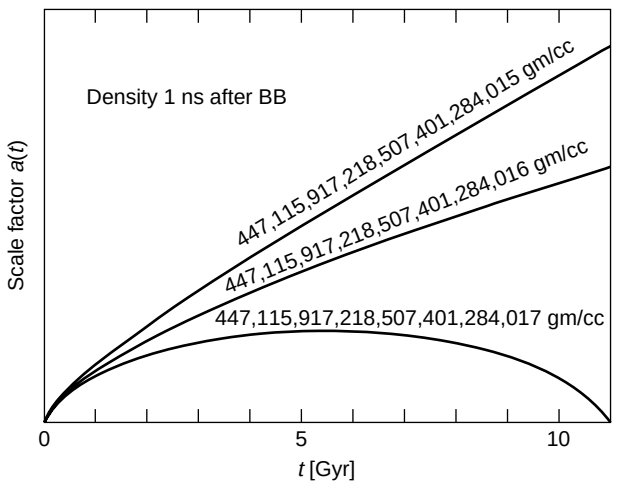

Fig. 6. Scale factors for three different initial densities for the Universe at 1 nanosecond after the Big Bang. A difference of only 1 gm/cc out 447 sextillion gm/cc makes a tremendous difference. The middle curve has the critical density, while the top curve is an open Universe and the bottom curve is a closed Universe that is recollapsing at the present time.

The second difficulty involves the almost perfect isotropy of the CMB. The intrinsic anisotropy of the CMB is a measure of both the temperature and the gravitational potential that existed in the Universe when it cooled to 3000 K. At this time, about 300,000 years after the Big Bang, protons and electrons could combine to form hydrogen atoms. Hydrogen is a transparent gas, while the plasma of protons and electrons that existed earlier would scatter the photons in the CMB like the water droplets in fog. But since this happened 300,000 years after the Big Bang, regions that are more than about 1 million light years apart could never have communicated with each other, and should have independent initial conditions. The distance that light could have traveled since the Big Bang is called the horizon, and objects past the horizon are not visible. A distance of 1 million light years would appear to span an angle of 2 degrees on the sky.

Thus objects more than 2 degrees apart on the sky had never seen each other when the Universe became transparent, but they still have the same CMB temperature to great precision. How did this happen? This is called the horizon problem.

Inflationary Scenario

There is a proposed solution to these problems known as the inflationary scenario. This version of the Big Bang model supposes that the Universe went into a Steady State like phase sometime earlier than one picosecond after the Big Bang. The most popular model has inflation occurring 10^{-35} seconds after the Big Bang. During this inflationary phase the scale factor would double, then double again, and again, until the scale factor doubled more than 100 times. The initial radius of curvature would double with each doubling of the scale factor, so the radius of curvature becomes very large. Thus the curvature, which is the inverse square of the radius of curvature, becomes essentially zero. The density is automatically driven to equal the critical density, and thus the flatness-oldness problem is resolved. The horizon problem is also solved by tremendous expansion during the inflationary epoch. Two objects separated by 0.01 cm could have communicated with each other in the first picosecond after the Big Bang, but would be 10 billion light years apart when the inflationary epoch ended after 100 doublings. So everything we can see in every direction was once part of a miniscule region prior to inflation, which explains the extreme isotropy of the CMB.

An inflationary era is generated when the vacuum has an energy density that dominates the total density of the Universe. Any vacuum energy density must be associated with a negative pressure, which leads to an effective gravitational repulsion. Thus instead of decelerating due to gravitational attraction, the expansion of the Universe accelerates due to this repulsion. This causes the many doublings of the scale factor during the inflationary epoch. At the end of the inflationary epoch, the vacuum energy density is converted into many high-energy particles, which provides the initial conditions for the normal hot Big Bang model.

One consequence of the inflationary scenario is that quantum fluctuations could be the cause of the small CMB anisotropy that we do see. This gives a prediction of the inflationary scenario, that small-, medium-, and large-scale anisotropies should contribute equally to the observed temperature differences. This "equal power on all scales" should apply to all angles much larger than 2 degrees, the horizon size when the Universe became transparent. The DMR on COBE observed only scales larger than 7 degrees, and the anisotropy observed by the DMR is very consistent with equal power on all scales. See Figure 7.

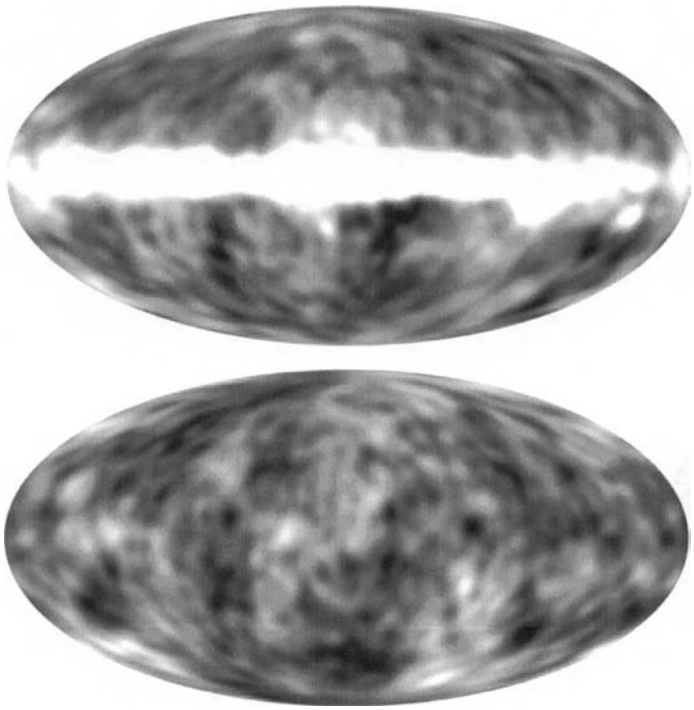

Fig. 7. Top panel shows the COBE DMR data with the dipole anisotropy removed, in a positive black & white image, so the white areas are brighter. Bottom panel shows the "equal power on all scales" model predicted by the inflationary scenario, which is quite consistent with the COBE data away from the bright emission from the Milky Way.

Dark Matter

When the Universe became transparent, the photons that came from denser, hotter regions also had to climb out of the gravitational potential well produced by the denser material. The photons lose so much energy climbing out of the potential well that the CMB coming from the denser regions appears to be cooler than the average in the maps produced by the DMR on COBE. The magnitude of the gravitational potential fluctuations shown by the DMR maps is small. If all the matter in the Universe is made of protons, neutrons, and electrons (which includes all of the chemical elements), then it is not able to respond to the gravitational forces until the Universe becomes transparent, and the final result is that there is not enough gravitational force to produce the observed clusters and superclusters of galaxies. But if most of the matter in the Universe does not interact with light, then it can respond to the gravitational forces before the Universe becomes transparent. Then it is quite possible to produce the observed clusters and superclusters of galaxies. This matter, which does not emit light, scatter light, or absorb light, is called dark matter. Because it cannot be made out of protons and neutrons (which are called baryons for "heavy" particles), this is non-baryonic dark matter.

For fluctuations of the correct size, an acoustic oscillation prior to the Universe becoming transparent can reverse the phase of the density effect. The acoustic oscillation occurs only in the normal matter plus the radiation in the CMB, not in the dark matter. Since the dark matter contains most of the mass, the gravitational potential well does not oscillate, so if a given wave has an oscillation period of 600,000 years, it will have gone through one-half cycle when the Universe becomes transparent, and the hot dense region will have become cool and tenuous. These cool photons will still have to climb out of a gravitational potential well, leading to a much increased anisotropy for waves of this particular period. The speed of sound is well known during this epoch, so one has a wave of known wavelength which projects into a particular angular scale on the sky. The angle subtended by this known wavelength depends on the curvature of the Universe, and it is about 2 degrees for a flat Universe, less than 2 degrees for an open Universe, and more than 2 degrees for a closed Universe. Recent results from measurements of the anisotropy of the CMB on angular scales much smaller than COBE's 7 degree limit have shown that the Universe is indeed flat. These results will be refined with data from the Microwave Anisotropy Probe (MAP), a satellite to be launched in 2001, and the European PLANCK mission to be launched in 2007.

Finally, observations of very distant Type Ia supernovae have shown them to be fainter than one would predict in a flat, dark–matter–dominated Universe which has a decelerating expansion. If the expansion of the Universe is accelerating instead, then the expansion was slower in the past, which makes light from distant objects travel further to reach us because the past size of the Universe was larger. If all of the current data are correct, then the composition of the Universe is 5% normal matter, 25% non-baryonic dark matter, and 70% vacuum energy. Further data from CMB anisotropy experiments will test this model and either confirm it or replace it before 2010.

Prospects

Thus the advances in cosmology have been stunning. In the year 1500 people thought the Solar System was the Universe and that the Earth was in its center. In the year 1900 people thought the Milky Way was the Universe and the Sun was near its center. In the year 2000 people think that the Universe has billions of galaxies like the Milky Way, and that 95% of the density of the Universe is in forms of matter or energy that we have never studied in our laboratories. New data will continue to arrive from CMB anisotropy studies, from supernovae, and from high-energy particle accelerators like Fermilab in the USA or the Large Hadron Collider in Europe. Our knowledge of the Universe will be greatly enhanced by these new data. See also **Astrobiology**; and **X-Ray Astronomy**.

COSTAL. Pertaining to a rib or the region of the ribs. Thus, costal cartilage is the cartilaginous portion of the ribs which joins them to the sternum. The term intercostal refers to the space between the ribs.

COSTAL ZONE COLOR SCANNER (CZCS). See **Nimbus Satellite Program**.

COTTER. A wedge-shaped metal piece for fastening two parts subjected to reciprocatory motion. The connecting rod bearing of a steam engine is often constructed with a removable cap held in place by a cotter. A cotter pin is a split pin made of semicylindrical bar stock, bent so that the flat surfaces are in contact, to permit insertion in a drilled hole. The cotter pin is used as a locking medium for nuts and bolts; since the pin is made of a soft steel, the split ends can be spread after it has been inserted in the hole.

COTTON *(Gossypium* species*; Malvaceae)*. A natural fiber, cellulosic in composition, with the general formula $(C_6H_{10}O_5)_x$, specific gravity, 1.54; moisture regain 7–8.5% (at 70 °F (21.1 °C) and 65% relative humidity); and a tensile strength of $60–120 \times 10^3$ psi (same condition of temperature and humidity). Cotton is quite resistant to degradation by heat. After about 5 hours at 121 °F (50 °C), the material yellows, and above 300 °F (149 °C), the material decomposes. Cold concentrated acids and hot dilute acids disintegrate cotton. In alkalis, cotton mercerizes without damage. The fiber is quite resistant to most solvents.

Even with the large inroads of synthetic fibers into the textile industry, cotton remains as a major textile fiber, consumption still being expressed in terms of billions of pounds per day. As one of the most versatile of fibers, cotton blends well with other fibers. In addition to the cellulosic content (88–96% depending upon source), cotton contains proteins, pectin, sugar, and wax (about 0.4–0.8%). Much research is going forth to eliminate much of the loss and damage that occur in harvesting and ginning. These factors contribute to price instability.

From the standpoint of use in textiles, cotton is rated excellent for hand (general feel, softness, drape), pilling resistance, and stability to repeated launderings. Cotton is rated good for abrasion resistance, strength, wash and wear performance, and wrinkle resistance. Resistance to sunlight is rated only fair. Pressed-crease retention is rated poor. Safe-ironing temperature for most cotton fabrics is 425 °F (219 °C).

Important worldwide producers include Brazil, Egypt, India, and the United States.

Many species of cotton plants are known, some native to warm regions of America; others growing wild in tropical Asia. Cotton seeds are surrounded by an abundance of soft white fibers, which when mature are very conspicuous. These fibers are unicellular and have been known and used for hundreds of years. Cultivation of cotton in India has continued through at least 26 centuries. Even before the discovery of America, the natives of tropical America were growing Sea Island cotton and using its fibers.

The cotton plant of cultivation is a woody annual growing 3 or 4 feet (0.9 or 1.2 meters) tall. It bears large palmate leaves and showy white flowers which turn pink as they grow older. Outside the five-parted corolla and calyx is an involucre composed of three large green bracts having very irregular margins. These bracts persist throughout the growth of the fruit. The stamens of the cotton flower have their filaments united to form a hollow tube through which the stigmas must grow; this stamen structure is characteristic of the mallow family, or *Malvaceae*. The fruit is a large dehiscent capsule of ovoid shape. On dehiscence, or splitting open, at maturity, the soft white fibers which surround the five or six large dark brown or black seeds become visible. The fibers are of two kinds, one relatively long, called lint, the other short and called fuzz. The capsule of the cotton plant is generally called the cotton boll. The length of the lint fibers varies in different species: Sea Island cotton, the native American species *Gossypium barbadense*, cultivated on coastal areas of the southern states, has the longest fibers of any cotton ($1\frac{1}{2}–2\frac{1}{2}$ inches; 3.8–6.4 centimeters long). Egyptian cotton fibers are slightly shorter than these. Next comes upland cotton, which is mainly derived from *Gossypium hirsutum*. This is the principal cotton plant of the southern states. In these the length of the fibers varies considerably, but averages about 1 inch (2.5 centimeters). Asiatic cottons have still shorter fibers.

Cotton cultivation is limited to regions having a growing season of 6 months or more of continuous high temperature. Any soil having a proper moisture content is suitable for cotton, but a deep, well-drained loam soil is best. One requirement is that excessive rainfall shall not occur during the period when the bolls are opening, since the cotton fibers are injured by moisture at that time. During the growing season the cotton fields must be kept clear of weeds. From 5 to 6 months are required before the production of fibers begins, after which fiber production continues for another 3 months or more.

The soft, light fibers, after picking, are carted to the gins. Previous to the invention of the cotton gin by Eli Whitney in 1793, the lint was removed from the seeds by hand, a slow and laborious process. The invention of the gin greatly advanced the cotton-manufacturing industry. The cotton gin is a steel grate with narrow slits through which reach thin-notched saws. The rapid rotation of the latter causes lint to catch on their teeth. The lints are pulled through the grating, after which brushes remove them from the saws. This ginned cotton is then pressed into bales weighing about 500 pounds (227 kilograms) each.

The uses of cotton are many. First among them is the manufacture of cloth. Cloth may be woven entirely of cotton, as much is, or may be of cotton mixed with other fibers, as synthetics, linen and wool.

Cotton fibers, especially the fuzz, are frequently used to stuff mattresses, pads and upholstered furniture. Treated with chemicals that remove the thin coating of waxy substances that cover the fibers, the latter becomes absorbent cotton, which is capable of absorbing many times its weight of water.

Cotton treated in this way is almost pure cellulose, and so is in great demand by those industries using cellulose. The pure cellulose of the fiber may be dissolved and then precipitated in sheets, giving the familiar thin transparent cellophane. Or the dissolved cellulose may be pressed through fine holes and solidified, giving rayon. If treated with concentrated caustic soda, cotton fibers take on a high degree of luster. The product of this process is called mercerized cotton, after John Mercer, its discoverer.

Treated with nitric acid under various conditions, cotton yields a long series of by-products. Some of them are plastic substances. If highly nitrated, cellulose becomes gun-cotton, used in the manufacture of explosives. Collodion is one of these nitrated products. Many varnishes and lacquers are made from cotton cellulose.

Not all the derivative products of cotton come from the fibers. Some, for example, are obtained from the seeds. In preparing these, the hulls are first removed from the kernel within. These hulls are used as fuel in the ginning mill, as food for cattle, and as fertilizer. The kernels are heated and pressed to remove the oil in cotton. During this pressing the kernels are wrapped in cloth to prevent anything but oil from being expressed. The oil is purified to a soft white substance very similar to lard in appearance. Cottonseed oil is used in making salad oils, oleomargarine and soap. After the oil is expressed, the seed cake may be used as food for stock or as a fertilizer.

COTTONSEED OIL. See **Vegetable Oils (Edible)**.

COTTON STAINER *(Insecta, Hemiptera; Dysdercus)*. A bug of Florida and adjacent states which punctures the bolls of cotton and causes staining of the fiber. There is another species in Egypt. It develops in groups which can be jarred from the plants into vessels containing a little kerosene.

COTTRELL, FREDERICK G. (1877–1948). A native of California Cottrell obtained his doctorate from Leibig in 1902. His major contribution to industrial chemistry was the discovery of a practical method of dust elimination by electrical precipitation. Used in factory stacks and other large units, this process has contributed greatly to purifying the atmosphere of industrial areas. The principle involves charging a suspended wire with electricity. This creates a field that ionizes the surrounding air, the particles assuming the charge on contact and then moving to the wall of the stack, where they are electrically discharged and precipitated.

COUDÉ. A modification of the equatorial form of mounting for an astronomical telescope, originally designed for the purpose of providing a maximum amount of comfort for the observer. Now, however, the Coudé focus has found great favor where there is a need to mount very large equipment, such as special spectrographs, without flexure. The telescope itself is mounted in bearings parallel to the axis of rotation of the earth, and forms the polar axis of the instrument. The eyepiece is at the upper end, and usually projects into a closed room. Below the object glass, a mirror is mounted in such a manner that it will rotate about an axis perpendicular to the optical axis of the telescope. Hence, the mirror may be rotated about its own axis parallel to an hour circle (in the coordinate of declination), and is carried along with the rotating tube parallel to the coordinate of hour angle. The observer, seated in a comfortably heated room, looks down into the eyepiece and sees the field of view slowly rotating about the optical center of the field.

The fundamental difficulty with the Coudé mounting is that the mirror will introduce distortion. Furthermore, unless the aluminum coating on the mirror is very nearly perfect, there will be a large amount of light loss.

COUETTE FLOW. A two-dimensional steady flow without pressure gradient in the direction of flow and caused by the tangential movement of the bounding surfaces. The only practicable type is the flow between concentric rotating cylinders, although the flow between parallel planes with uniform relative velocity is used in the elementary discussion of viscosity.

COULOMB, CHARLES (1736–1806). Coulomb was a French physicist. His early career was as a military engineer. He supervised workers as they constructed and repaired forts. Because of poor health, he changed his career direction and began studying the strength of materials in relationship to architecture. His early experiments involving the stresses required to break a substance led to the modern science of the strength of materials. By 1877, discoveries made while experimenting with the magnetic compass led to the invention of the torsion balance, which is used for measuring very small weights. The torsion balance led him to some of his most important work, including the effects of friction on machines and his theory of lubrication.

Coulomb's life work on electrostatics and magnetism confirmed their relationship. Between 1785 and 1789 he published seven papers on electricity and magnetism and established Coulomb's law for which he is best remembered for today.

See also **Electromagnetic Phenomena**; **Electrostatics**; **Friction (Mechanical)**; and **Torsion Balance**.

J. M. I.

COULOMB COLLISION. The collision of two particles both of which are charged. In this case the collision cross section is considerably larger than when one of the particles is neutral because the electric field of the two particles can interact at much larger distances. Since the collisions are distant ones, however, the particles will suffer only a small angular deviation.

COULOMB DAMPING. The dissipation of energy that occurs when a particle in a vibrating system is resisted by a force whose magnitude is a constant independent of displacement and velocity, and whose direction is opposite to the direction of the velocity of the particle. Also called *dry friction damping*.

COULOMB DEGENERACY. Identity of the energy levels of a charged particle bound in a Coulomb (electrostatic) field for different values of the orbital angular momentum, provided that the principal quantum number and spin state are the same, e.g., the $2s_{1/2}$ and $2p_{1/2}$ states of the hydrogen atom. See also **Lamb Shift**.

COULOMB ENERGY. That part of the binding energy of a solid associated with the electrostatic interaction of the ions and electrons.

COULOMB EXCITATION. This terminology is commonly used to refer to the process of raising a target nucleus to an excited state through an electromagnetic interaction with a passing charged nuclear particle. If the process is purely coulomb excitation, the passing particle remains outside the range of the nuclear forces of the target nucleus, so is not strictly a nuclear reaction.

COULOMB LAW (Electrostatics). The force between two point (electric) charges in free space is a pure attraction or repulsion, and is given by

$$F = \frac{q_1 q_2}{4\pi\varepsilon_0 r^2} \text{ newtons}$$

where q_1 and q_2 are the magnitudes of the charges in coulombs, r is their separation in meters and ε_0 is the permittivity of free space, 8.84×10^{-9} farads/meter.

COULOMETER. Also known as coulombmeter, a device for the measurement of electric current. Originally developed (1916) by the U.S. National Bureau of Standards, the *silver coulometer* consists of a small platinum vessel, acting as the cathode, into which a pure silver anode is immersed. An aqueous solution of silver nitrate (15% $AgNO_3$, wt) of very high purity is used as the electrolyte. In use, both the quantity of silver deposited and the time are carefully noted. These measurements permit a calculation of the average current strength.

The more practical form for laboratory use employs copper electrodes in a bath of copper sulfate. The thin copper cathode, between two heavy copper anodes, is removable for weighing; and since one coulomb deposits 0.000329 gram of copper, the weight of the copper deposit enables one to determine the quantity of electricity in coulombs. A solution recommended for this cell consists of 15 grams of crystalline copper sulfate, 5 grams of pure sulfuric acid, and 5 grams of pure alcohol, dissolved in 100 grams of distilled water.

The effect of current flow on electrolyte concentration also can be determined by titrating the electrolyte after electrolysis. A device of this type is known as a *titration coulometer*. Rarely, a coulometer may be referred to as a *voltmeter*.

COUNTDOWN. 1. A step-by-step process that culminates in a climactic event, each step being performed in accordance with a schedule marked by a count in inverse numerical order; specifically, this process is used in leading up to the launch of a large or complicated rocket vehicle, or in leading up to a captive test, a readiness firing, a mock firing, or other firing test.

2. The act of counting inversely during this process. In sense 2, the countdown ends with T-time; thus, T minus 60 minutes indicates there are 60 minutes to go, excepting for holds and recycling. The countdown may by hours, minutes, or seconds. At the end, it narrows down to seconds, 4-3-2-1-0.

COUNTER. A device or instrument for summing the number of pieces, events, pulses, and a variety of other phenomena and occurrences that may occur within a fixed period of time. A counter may identify and hence remember each item of concern in its effort to attain a sum, or it may determine a rate and from this infer a total. Be it ever so simple, a counter requires a memory (if direct counting is done)-the reason children use their fingers sometimes in counting. Counters as used in data processing systems are described under **Counter (Computer System)**.

The counting scale is an excellent example of an inferential means for counting discrete pieces. Provided that the pieces to be counted are of reasonable uniformity and that variations of weight between individual pieces are small when compared with the weight of each piece, weighing provides a very satisfactory counting method and often one that is convenient and efficient. Scales with special readouts are furnished for parts counting.

Because of the large variety of needs for counting, numerous types of counters, ranging from purely mechanical through electric and electronic and from low cost to a high degree of sophistication, are available.

Electronic Counters. These units were initially developed for use in conjunction with Geiger or Geiger-Mueller counting tubes. Originally, electronic counters were constructed with binary counting elements. Contemporary counters utilize decimal-type counting tubes or equivalent solid-state circuitry. Electronic counters generally consist of a time-base generator, a signal gate, and decade-counting units. Frequency is measured by counting the number of input cycles over a precisely controlled period of time. The time-base generator develops control signals which are applied to the signal gate. When the first or "start" signal is received, the signal gate opens to pass input pulses from the unknown frequency source to the decade-counting units. When the second or "stop" signal is received, the signal gate closes to prevent further input pulses. Totalization of input pulses by the decade-counting units during the interval is a measure of the input-signal frequency. Frequency measurement accuracy of an electronic counter is plus or minus one count plus or minus the accuracy of the time-base generator. In some standard models, frequencies up to 500 MHz or more are measured with a 10-MHz counter and a frequency converter. With a transfer oscillator or other harmonic generator-mixer arrangements, the range is further extended to at least 40 kMHz.

Mechanical Counters. For numerous applications, simple mechanical counters are relatively low cost and most appropriate. Typically, mechanical counters have operating speeds of approximately 1,000 counts per minute or 100 revolutions per minute of the prime wheel. The life of a commercial mechanical counter can be considered to range between 20 and 100 million counts, with an average of about 50 million counts. For a counter of precise and high-quality production, the figure could go to 500 million counts. Counters of this type are widely used on a large variety of machines, ranging from printing presses, packaging equipment, conveyors, machine tools, to turnstiles, etc.

A mechanical counter is comprised of three major elements: (1) drive, (2) transfer mechanism, and (3) reset. A direct drive operates through a direct connection between the drive shaft and the first (or "unit") wheel of a counter. This type of drive provides 10 counts per revolution of the drive shaft and is frequently used when indication applications and interpolation between full-figure readings may be required. Revolution drives are often provided through 10:1 gearing between the drive shaft and the first counter wheel. One count per revolution results. Industrial applications where machine shaft revolutions are counted often require this type of input. Geared drives giving ratios other than 10 counts per revolution or 1 count per revolution can be devised and are common in certain applications. Ratchet counter drives provide counts of cycles of oscillating or reciprocating motion. The counting stroke is generally composed of "pretravel," the "counting stroke" proper, and of "overtravel." The counting stroke proper is frequently 36°, with the pretravel and overtravel something less than this amount. Return motions are frequently actuated by internal return springs. Some units count on the return stroke, using the counting (or power) stroke to cock the return spring, which drives the wheels when it is released. Rotary ratchet drives are similar. The main difference is the elimination of mechanical stops for the counting motion.

Electromechanical Counters. The basic difference between an electromechanical counter and the previously described mechanical counters is in the input means. The electromechanical form is usually operated by an electrical impulse instead of a mechanical motion. In cases where events or units are being counted, it is usually possible to substitute an electromechanical counter for a mechanical unit by having the mechanical drive member operate a switch which is used to control on-off voltage pulses which are then applied to the counter. An advantage of this type of operation is that the counter need not be mounted in conjunction with the sensing element, but can be remotely located. Electromechanical counters are often mounted in multiple groups and are used to provide summarizing information on production statistics, or for general multiple-channel data storage and indication.

Although some electromechanical counters use iron-core solenoid driving units, it is more common to find clapper-type solenoids, such as those used in relay construction. Either single- or double-stroke drives may be used. In the single-stroke mechanism, the pull-in of the clapper rotates the lowest-order wheel by 36° through a ratchet and pawl linkage. The return stroke of the clapper is accomplished by spring action and the wheels are at rest during the return stroke. Two-stroke drives move the wheels 18° on the power stroke and the additional 18° on the return stroke.

Stepping motor drives also are used and these are capable of high speed because they have no ratchets and pawls. Electromechanical counters are basically dc operated, but models are obtainable for operating on alternating current. Direct current counters can be equipped with compact full-wave rectifiers for ac operation.

Bidirectional magnetic counters (add-and-subtract counters) also are available. They are usually equipped with two power sources, one of which adds counts and one of which subtracts counts from the total reading. Units of this type are particularly useful for stock and inventory control applications.

The "single-wheel" unit also has many applications. In its basic form, this is a counter having a single digital counting wheel and a switch capable of being actuated between the nine and zero position. This transfer switch can be used to operate a higher-order single-wheel counter, and thus units with any desired number of digits can thus be built up.

COUNTERBALANCING. Counterbalancing means simply the application of extra mass to a system in order to produce balance for the system as a whole, and to offset the unbalance arising from some particular part. Rotating machinery, especially high-speed machinery, needs to be counterbalanced if the center of gravity of the rotating mass does not lie on the axis of rotation. Hoists are frequently counterbalanced so that a descending weight will supply some of the energy required for hoisting the nonuseful load. Numerous examples of counterbalancing will be found in everyday practice, but those cases associated with the counterbalancing of high-speed rotating machinery are the most imperative of solution. Counterbalancing mechanisms are very important in certain balances and scales.

COUNTERBORE. Counterboring, spot-facing, countersinking, and center drilling are hole-enlarging operations generally performed on a drill press, although they are actually reaming operations. Counterbored holes are those with cylindrical enlargements, for fillister head screws; spot-faced holes are counterbored to a depth just sufficient to clean up the surface. Countersunk holes have conical enlargements; center drilling is essentially countersinking, using an integral drill and countersink for machining center holes for turning operations on lathes.

Both counterboring and countersinking are performed with piloted cutters, but usually (except for center drilling) require separate operations for drilling the body hole before countersinking or counterboring. A subland drill is a twist drill of special design, constructed so as to provide separate cutting edges and flutes for each hole diameter, so that counterbored holes may be produced in one operation.

COUNTER (Computer System). A physical or logical device that is capable of maintaining numeric values which can be incremented or decremented by the value of another number. A counter, located in storage, may be incremented or decremented under control of the program. An example of such use would be recording the number of times a program loop has been executed. The counter location is set to the value of the number of times the sequence of instructions is to be performed. Upon completion of the sequence, the counter is decremented by one and then tested for zero. If the answer is nonzero, the sequence of instructions is repeated.

A counter also may be in the form of a circuit that records the number of times an event occurs. A counter that counts according to the binary number system is illustrated by Fig. 1. Counters also may be used to accumulate the number of times an external event takes place. The counter may be a storage location or a counter circuit that is incremented as the result of an external stimulus.

Specific counter definitions include:

The *binary counter* is (a) a counter which counts according to the binary number system, or (b) a counter capable of assuming one of two stable states.

The *control counter* records the storage location of the instruction word, which is to be operated upon following the instruction word in current use. The control counter may select storage locations in sequence, thus obtaining the next instruction word from the subsequent storage location, unless a transfer or special instruction is encountered.

The *location counter* or *instruction counter* is (a) the control section register which contains the address of the instruction currently being

	A_3	A_2	A_1
P1	0	0	1
P2	0	1	0
P3	0	1	1
P4	1	0	0
P5	1	0	1
P6	1	1	0
P7	1	1	1
P8	0	0	0

Fig. 1. Truth table for a binary counter. The situation illustrates a binary counter of three-stages capable of counting up to eight pulses. Each trigger changes state when a pulse is gated to its input. In the instance of trigger A_2, it receives an input pulse only when trigger A_1 and the input are both 1. Subsequently, trigger A_3 changes its state only when both trigger A_1 and A_2 and the input pulse are all 1's. This table shows the value of each trigger after each input pulse. At the eighth pulse, the counter resets to zero.

executed, or (b) a register in which the address of the current instruction is recorded. Synonymous with instruction counter and program address counter.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

COUNTRY ROCK. The general term used for the main mass of rock in which occur the veins, dikes or ore bodies which are of particular interest, or which are described in detail.

COUPLE. Two parallel forces of equal magnitude, but opposite direction cannot be reduced to a single force, i.e., as the resultant of two forces acting at their center of pressure. Such forces form a couple. The effect of a couple upon a body is independent of the location of that couple with respect to the body. The net action of several couples all in the same plane on a body is equal to the algebraic sum of the moments of the couples, the sign being determined from the direction of rotation which the couple tends to give. The moment of a couple is the production of the perpendicular distance between the forces and one of the forces. The action of any force, acting at any particular point on a body, upon another point lying in the plane of the force can be reproduced by another force of the same magnitude acting at the desired point plus a couple. For example (see Fig. 1.), let F be any force acting at point a, and b any other point at distance d from the line of action of F. At point b place two equal and opposite forces, F and F', which are parallel to the direction of the original force F. Then F' at b and F at a form a couple Fd, leaving F, which acts through point b. The effect on point b of the latter force and the couple is the same as the effect of the original force F acting at a. Thus it is seen that it is possible to replace a force acting at a with an equal force acting at b, and the couple Fd, where d is the perpendicular distance from b to the force F in its original position.

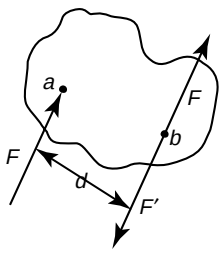

Fig. 1. Forces acting in a couple.

COUPLED CIRCUIT. While any group of circuits which are so connected or related that effects in one produce effects in the other constitute a coupled circuit, the term is usually used to designate circuits related so ac effects are transferred but steady state D.C. effects are not. The two most common classifications of coupled circuits are the inductive and the capacitive coupled circuits, so named because of the primary method of transferring the effects. Capacitance coupling is used quite extensively in various vacuum tube amplifier circuits, in thyratron circuits, and similar applications where it is desired to block DC effects and transfer A.C. Since the capacitor does this it may be used as the common element between the two circuits. The so-called resistance coupled amplifier is really capacitance coupled. Figure 1 shows examples of this type. Inductive coupling is the most widely used type since it is used extensively in the power field as well as in the communications and electronics fields. The ordinary power transformer is the means of inductively coupling two power circuits. The various transformers, tuning coils, etc., of radio circuits are other examples. Figure 2 shows some typical circuits.

Fig. 1. Capacitance-coupled circuits.

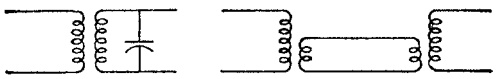

Fig. 2. Inductance-coupled circuits.

For two circuits to be inductively coupled an inductance element in one circuit must be so related to an inductance in the other that flux set up by one links the other. Thus a current flowing in circuit number 1 produces a flux which, in part at least, links the other.

When this flux changes it produces a voltage in the second coil, and if the second circuit is closed a current flows. This flux which links both circuits is the mutual flux and the effect gives rise to mutual inductance. Mutual inductance may be defined as the flux linkages in one circuit per ampere in the other,

$$M = N_2\phi_m/I_1$$

where M is the mutual inductance, $N_2\phi_m$ the flux linkages by the mutual flux in circuit 2 and I_1 is the current in circuit 1 which caused the flux ϕ_m. M is also expressible in terms of the self-inductance of the coupled coils,

$$M = K\sqrt{L_1L_2}$$

where k is the coefficient of coupling and the L's are the respective self-inductances. The manner in which the current in the secondary circuit varies is a rather complicated function of the various circuit parameters, frequency, and primary current. However, there is a certain value of coupling which will produce a maximum secondary current for fixed values of the other parameters. This value of coupling is called the critical coupling. In the usual inductive coupled circuit used at radio frequencies where the circuits are tuned, the secondary current, plotted as a function of frequency, presents a single peak, increasing in value, up to the critical coupling, then presents a double peak with no increase in value as the coupling is made still closer.

Not only are coupled circuits used to transfer ac energy from one circuit to another, but by proper design may be made to match the impedances of the connected circuits also. See also **Impedance Matching**.

COUPLED ION-NEUTRAL DYNAMICS INVESTIGATION (CINDI). See **Space Science Missions: Sun**.

COUPLED OSCILLATOR (Mechanical). A system with two or more components coupled by forces that can be considered either exactly or approximately as harmonic. The resultant motion of each component when the system is displaced from its equilibrium position can be considered as a linear superposition of simple harmonic oscillations with characteristic frequencies known as normal frequencies. For a nondegenerate, nondissipative coupled system of n particles each having one degree of freedom, there will exist n normal frequencies. It is theoretically possible by the correct choice of initial conditions to set a coupled system into oscillation so that all the particles vibrate with

only one normal frequency. Such a vibration is called a normal mode of vibration. For the n particle system there will exist n normal modes and n normal-coordinates. A normal coordinate vibrates harmonically with a single normal frequency and can be found by a transformation of the actual displacement coordinates that describe the individual motion of each particle.

COUPLING (Chemical). Reactions for the formation of chemical compounds usually by establishing a valence bond between a carbon atom and a nitrogen atom. Phenols and several other organic substances are also said "to couple." Polyphenylene oxides, thermoplastic materials, are produced by means of oxidative-coupling technology.

COUPLING (Mechanical). In mechanical engineering there are a number of uses of the term coupling. A pipe coupling is a hollow cylinder with internal pipe threads, used to join two sections of externally threaded pipe, either of the same or of different sizes; in the latter case, the unit is referred to as a reducing coupling. Shaft couplings are used to connect rotating shafts, and are of two types — rigid and flexible. The sleeve coupling is an example of the former type, and consists of a hollow cylinder, usually provided with a keyway and set screws to prevent relative rotary and axial motion of the shafts. Another type of rigid coupling, the flange coupling, consists of a disk and hub on each shaft, connected by through bolts. Since perfect alignment of two theoretically collinear shafts is difficult to attain, some form of flexible coupling is usually employed for moderate or heavy duty transmissions, such as motor-generator sets, motor-driven pumps, and the like, to prevent the transmission of shock and eliminate stress reversals. There are numerous commercial forms of flexible couplings; one type is similar to a flanged coupling, but employs laminated steel pins instead of through bolts for transmitting power from one flange to the other. In another form, two sprockets of equal size are mounted — one on each shaft — and connected by means of a roller or silent chain. In other forms, the connection between the shaft flanges is effected by springs or by bolts or pins mounted in rubber.

For connecting shafts whose axes are slightly out of alignment, but approximately parallel, the Oldhams or cross-keyed coupling is used. This device consists of two coupling halves fastened to the shafts; each half has a groove or slot cut in it, and the two halves are arranged so that the grooves are perpendicular. The halves are connected by a central member, with perpendicular tongues that engage the coupling half slots. In some instances, cross-keyed couplings are used as flexible couplings; in such cases, the central member is made of fiber or has leather-faced contact surfaces.

A universal joint is a rigid coupling for connecting shafts whose axes will intersect if prolonged, and for applications where the angle between the shaft axes may vary during operation. The device is usually composed of two forked coupling halves, with a central block free to oscillate about two mutually perpendicular axes lying in a plane perpendicular to the shaft axes. Universal joints operate satisfactorily when the shaft coincidence error does not exceed 10 to 15 degrees; beyond this range, the joint is likely to be quite inefficient.

COUPLING (Physics). An interaction between parts or systems. A simple illustration arising in induction heaters and other electrical apparatus is where coupling is the percentage of the total magnetic flux produced by an inductor which is useful in heating a load or charge, or which is otherwise effective. In atomic physics, the various parts of a system (e.g., electrons in an atom) each have orbital angular momentum and spin, or rotation, angular momentum. Obviously these values can be combined in various ways to obtain a resultant momentum, which is useful in computing various properties (optical, magnetic, etc.,) of the substance composed of these systems.

In *Russell-Saunders coupling* the orbital angular momentum and the spin angular momentum vectors of the individual particles are added separately to obtain a resultant orbital and a resultant spin angular momentum vector. The two resultants are then combined vectorially to obtain a series of allowed total angular momentum vectors.

In *spin-orbit coupling* the resultant angular momenta of the various individual particles are first found by adding the individual orbital angular momentum and spin angular momentum vectors, and then the resultants for each particle are combined to find total angular momentum vectors for the system.

Since Russell-Saunders coupling and spin-orbit coupling represent extremes, many transition cases occur, and must be reckoned with in studies of atoms. Moreover, often the spin angular momentum of the atomic nucleus must be considered. Obviously these processes are complex even for atoms; for molecules they are so involved that many different modes of coupling must be distinguished. This work was first done by Hund, who distinguished various coupling cases known by his name.

In *electroacoustic transducers*, performance is closely related with the tightness of coupling between mechanical and electrical aspects. Consider a piezoelectric disk which is compressed by putting in mechanical energy W_m. The appearance of surface charges shows that electrical energy W_e is stored in the self-capacitance and is available when an external circuit is connected to suitable electrodes. The ratio W_e/W_m (electromechanical coupling coefficient) sets a limit to the efficiency for a given bandwidth (frequency range). The coefficient may reach 70% for lead zirconate titanate. See also **Resonance**.

COUPON. An extra piece of metal formed on a casting, forging, or similar metal product for the purpose of furnishing material to make a metallurgical test specimen.

COURSE. The term course is used in a number of contradictory senses by different writers on the general subject of navigation. The U.S. Navy has adopted two standard meanings for this term: (1) course is the direction that a navigator desires his ship to follow for a given period of time; and (2) course is also the direction that a navigator hopes his ship has followed for a given period. Specifically, by the first definition, the navigator knows or assumes that his ship is in a given location at a given time, and he wishes to proceed to another particular location. By graphical methods, on a chart or small-area plotting sheet, or by any one of a number of standard computational methods (e.g., plane sailing, middle-latitude sailing, mercator sailing, great-circle sailing, and composite sailing), the navigator obtains the direction and length of the line joining the two points. These are known as the predicted course and distance between the two locations. By the second definition, the navigator knows, or assumes, that his ship is at a given location at a certain time. With the ship proceeding on a given heading with a known speed, the navigator may determine, by graphical or computational dead-reckoning methods, a position of the ship at the end of a definite period of time. The direction and length of the line joining the two locations are the assumed course and distance between the two points, or the dead-reckoning course and distance made good.

Also check following topics in alphabetical index: Current correction angle; Dead reckoning; Departure; Fix; Great-circle course; Heading; Plotting sheet; and Wind correction angle.

COURSE (Composite). The shortest track between two points on the surface of the earth is a great circle, if we neglect the slight oblateness. However, the following of such a track has two fundamental disadvantages: (1) Such a course is a rhumb line only in the particular cases of two points both on the equator, or two points on the same meridian of longitude. (2) Such a course will frequently lead the vessel into impossible positions (e.g., if the two points are in the same latitude but differ by 180° in longitude, the great-circle track between them would lead over the nearest pole).

A composite course is a combination of great-circle and rhumb line courses designed to carry a ship from one point to another by the shortest practicable path. In case the great-circle track does not lead the ship into impossible positions, the composite course is usually a series of rhumb line courses to successive positions along the great-circle track, the rhumb-line distances so figured that the course of the ship will be altered at convenient times (e.g., the changing of the watch). In case the great-circle course leads the ship into danger, the problem of computing the composite course is one of a number of compromises, which are different for every problem. A good example of such a composite course may be obtained by examining the shipping lanes across the oceans, which will be found on many terrestrial globes.

See also **Course**; **Navigation**; and **Rhumb Line**.

COVARIANCE. As an extension of the variance, the covariance of two variables x and y is the expectation of $(x-\mu_x)(y-\mu_y)$ where μ_x and μ_y are the means of x and y. For a sample of n values it is defined as $\sum_{i=1}^{n}(x_2-\overline{x})(y_2-\overline{y})/n$. Some authorities define it with a denominator of $n-1$ instead of n. See also **Variance**.

COVELLITE. The mineral covellite, cupric sulfide, CuS, is hexagonal, usually in thin platey crystals, but may be massive. It has a hardness of 1.5–2; specific gravity, 4.6; luster, submetallic to resinous; color, dark indigo blue, sometimes showing a purplish tarnish, or if moistened may appear purple in color. Its streak is dark gray to black; it is opaque. Covellite is found associated with chalcopyrite, bornite, and chalcocite, and is believed to be chiefly of secondary origin. Covellite occurs in Yugoslavia, Saxony, Sardinia, Argentina, Chile, Bolivia and Peru, and in the United States at Butte, Montana, and in Colorado, Wyoming, and Utah. This mineral was named for Covelli, who discovered it in the lavas of Mt. Vesuvius.

COWBIRD *(Aves, Passeriformes).* 1. The yellow wagtail of England. 2. A dark-colored bird, *Molothrus ater*, of southern Canada and the United States, related to the blackbirds, and several species of the same genus extending from Texas into South America. Most of these species deposit their eggs in the nests of other birds like the European cuckoo. They are named from their frequent association with cattle and before the settlement of North America the common species was called the buffalo bird.

COWPER'S GLANDS. Two small glands located beneath the male urethra, which produce a mucous secretion into the urethra; analogous to Bartholin's glands in the female.

COWRY *(Mollusca, Gasteropoda).* Compactly oval shells with a long narrow aperture, smooth surface, and often bright colors.

There are many species of cowries, especially in the Pacific and Indian Oceans. The shells of some have been used as money and for decorations.

COX, ALLEN V. (1926–1987). Cox was an American geophysicist who earned his bachelor's, master's, and doctorate degrees in geology and geophysics from University of California, Berkeley.

He established the USGS paleomagnetic laboratory and collected rock samples from all over the earth studying their magnetic characteristics. His work showed that the earth's magnetic field has gone through several reversals.

After 1967, he joined the faculty at Stanford University and continued researching magnetism in rocks. His work was eventually used for commercial and military interests.

See also **Earth**.

J. M. I.

COXSACKIE VIRUS. This virus was so named because the first strain was isolated in Coxsackie, New York in 1969. Since that time, newly discovered enteroviruses have been identified by number rather than by specific names. Coxsackie viruses have many biological characteristics in common with echoviruses. See also **Virus**. Coxsackie virus is usually spread by the hand-to-mouth route and infections occur most commonly in the summer and fall. Family groupings of cases or small epidemics are frequently associated with this virus. In addition to enteric system involvement and disease, extraenteric symptoms and disease may occur in some cases of coxsackie virus infection. Coxsackie virus A16 has been implicated in Kaposi's varicelliform eruption (skin). Coxsackie virus B types have been associated with infections of the nervous system. These may be manifested in aseptic meningitis as well as involvement in encephalitis, myelitis, and ganglionitis. See also **Dermatitis and Dermatosis**.

CRAB *(Crustacea, Decapoda).* Crustaceans with a short broad cephalothorax and a small abdomen bent below it. The large pinchers and four pairs of legs are the only conspicuous appendages. Most species of crabs are found in or near the ocean but some are terrestrial and others live in fresh water. The land crabs deposit their eggs in the water. The many species of crabs constitute a division of the order named the *Brachyura* from the short abdomen.

A number of species of crabs are used for food. Of these the edible crab of the Atlantic, which ranges from Cape Cod to Louisiana, and the edible crab of the Pacific Coast, are the most important species.

Many crabs have received common names that apply to one species or to a group of similar species. Among these names are: spider crab, hermit crab, fiddler crab and land crab. Commercially important crabs are described in the entry on **Crustaceans (Edible)**.

CRACHIN. In the China Sea, especially in Hainan Strait and the Gulf of Tonkin north of 20°N, a period of drizzle or light rain with low stratus clouds and bad visibility that frequently occurs between late January and early April and may persist for several days.

It is associated with a fall of pressure over China and a change from a continental to a maritime air mass.

CRACKERS AND COOKIES. See **Bakery Process,Yeast-Raised Products**.

CRACKING PROCESS. A reaction in which a hydrocarbon molecule is broken or fractured into two or more smaller fragments. Sometimes the term *pyrolysis* is used for this reaction. Possibilities for cleavage of a molecule include: (1) a carbon-hydrogen bond; (2) a bond between an inorganic atom and a carbon or hydrogen atom; and (3) a carbon-carbon bond. Usually the objective of cracking is that of reducing the size of hydrocarbon molecules; hence the target is to fracture the carbon-carbon bonds. The main cracking processes are: (1) thermal cracking; (2) fluid catalytic cracking; and (3) hydrocracking.

Thermal Cracking. Of the thermal cracking processes, two are of major importance: (1) coking, and (2) visbreaking (viscosity breaking). Both of these processes convert nondistillable residues into more valuable products. Thermal cracking was the first of the principal cracking processes used in the petroleum industry. For increasing gasoline production and improving quality, fluid catalytic cracking has essentially replaced thermal cracking.

In *thermal coking*, heavy residual stocks are converted into gas, gasoline, distillates, and coke. Generally, the objective is that of maximizing the yield of distillates; and minimizing the production of gas, gasoline, and coke. Light distillates are used for both domestic and industrial heating oils. There are two types of thermal coking processes: (1) cyclic, semicontinuous process, sometimes referred to as *delayed coking*, decarbonizing, or low-pressure coking; and (2) a continuous fluid coking process. About 70% of the installed capacity in the United States is the delayed coking type.

As shown by Fig. 1, a delayed coking unit is comprised of three sections-a furnace, coke drums, a fractionating unit, plus coke removal and handling equipment. Usually the feedstock is charged to the lower part of the fractionator. Here the feedstock is contacted by hot vapors from the coke drum, causing any light components to be flashed from the feed before the feed joins with the recycle and charged (from the bottom of the fractionator) to the furnace. The charge in the furnace is heated to about 480 °C (896 °F). The heated effluent from the furnace is introduced into the bottom of one of two or more insulated vessels (coke drums) where, as the result of its contained heat, the material cracks to form a solid

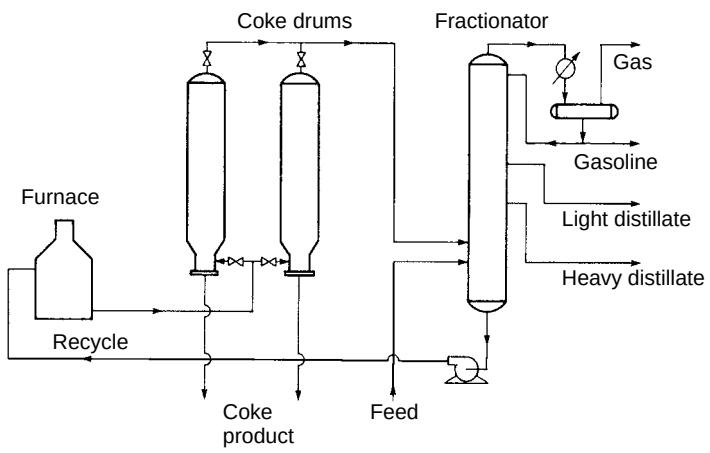

Fig. 1. Delayed coking unit shown schematically.

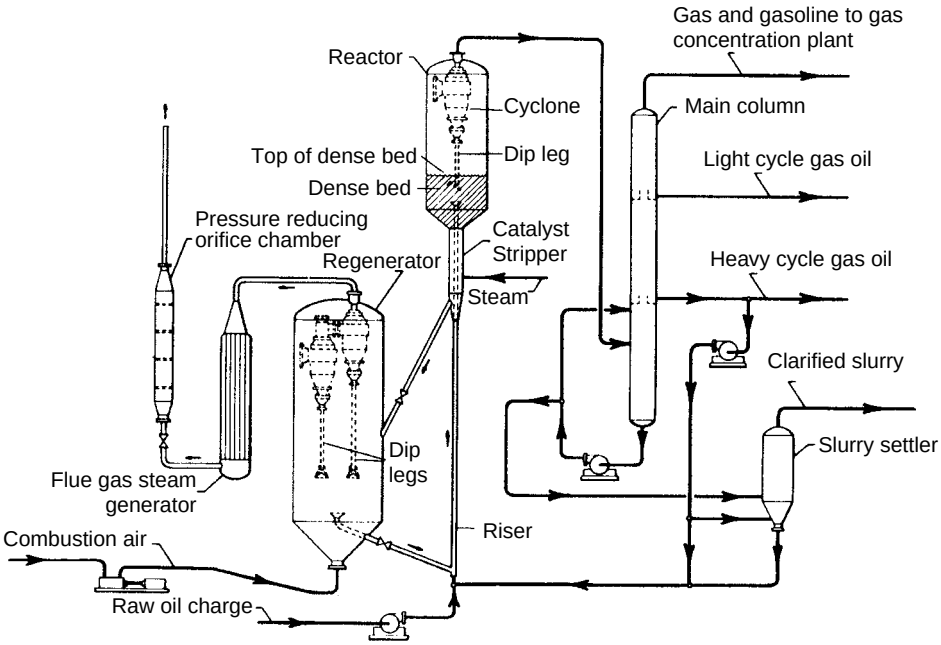

Fig. 2. Fluid catalytic cracking process. (*UOP Inc.*)

coke residue. At the same time, lighter cracked products are evolved and proceed from the top of the coke drums to the fractionator. The reaction in the coke drum is endothermic and thus the temperature of the material drops to about 425 °C (797 °F). The cracked products leave as vapors; the coke remains in the drum. The fractionator separates the cracked vapors into several side streams as shown on the diagram. When accumulated coke reaches a certain level in the drum, that drum is temporarily taken off-stream and the flow is switched to the second drum. Prior to removal of coke, the drum is steamed to remove vapors. Water is also added to cool the coke.

The fluid coking process accomplishes the coking operation in a continuous manner. Feed is sprayed into a fluid bed of hot coke in a coking reactor. Steam introduced into the bottom of the reactor provides the fluidization energy. The cracked products are quenched in an overhead scrubber and then go to the fractionator. The coke is deposited on the particles in the reactor, which commute with a heater vessel in which a portion of the coke is burned to heat up the returning coke particles to supply the energy for the coking reaction.

Fluid Catalytic Cracking. This process is used principally to create gasoline, C_3/C_4 olefins, and light distillates by the selective decomposition of heavy distillates. The process was introduced during World War II to replace earlier thermal cracking processes. Specially prepared catalysts are used. The resulting gasoline contains substantial proportions of high-octane-number hydrocarbon components, including aromatics, branched paraffins, and olefins. The cracking proceeds in accordance with the carbonium-ion mechanisms. Consequently, there are minor amounts of fragments lighter than C_3 in the products. This is to be contrasted with thermal cracking by the free-radical mechanism, wherein large proportions of fragments lighter than C_3 result. Another product of fluid catalytic cracking is *cycle oil,* a distillate that boils above gasoline. Cycle oils are withdrawn as net products and are used as components in heating oils, feedstocks to hydrocracking units, and for blending with heavy residuals as a means of reducing viscosity. The highly aromatic clarified slurry oils have been found to be useful feeds for the manufacture of carbon black.

Indicated in Fig. 2 is a representative fluid catalytic cracking unit, comprising: (1) a reactor; (2) a regenerator; (3) the main fractionator; (4) an air blower or compressor; (5) a spent-catalyst stripper; (6) catalyst recovery equipment, including cyclones internal in the reactor and regenerator; and slurry settler, and possibly an electrostatic precipitator; and (7) a gas-recovery unit. The catalyst used is essentially a specially prepared composite of silica and alumina.

In operation, preheated feedstock meets a controlled stream of hot, regenerated catalyst. Vaporized oil and catalyst ascend in the riser, such that the catalyst particles are suspended in a dilute phase. Essentially all of the cracking occurs in the riser. The catalyst particles are separated from the cracked vapors at the end of the riser and the catalyst containing a coke deposit is returned to the regenerator. The cracked vapors pass through one or more cyclones located in the upper portion of the reactor and proceed to the fractionator (main column) that produces the side streams indicated.

Hydrocracking. Processes in this category produce gasoline and light distillates from feed distillates that are higher-boiling than the products. Hydrocracked products are not olefinic. The light gaseous hydrocarbons produced by hydrocracking are entirely paraffinic. The processes operate at elevated pressures in the presence of hydrogen and catalysts. Temperatures are usually lower than 482 °C (900 °F). Pressures run from 800 to 2,500 psig. Both fixed-bed and ebullating-bed configurations are used. Because carbonaceous deposits accumulate very slowly on the catalyst, the on-line periods for these units are quite long, ranging from several months to over a year. Somewhat more costly to build than fluid catalytic cracking, the hydrocracking process has the advantage that it can handle heavier and dirtier feedstocks and also may be adapted to varying product ratios of gasoline to middle distillate.

Technical Staff, UOP Inc., Des Plaines, IL

Editor's Addendum. For any given petroleum processing design, there are competing designs, including cracking processes. Each particular design will have its own specific advantages and limitations (products yielded, product specifications, operating conditions, economic factors, etc.). Once developed by a design group, a given process generally will be licensed to end users or refinery construction and engineering firms, as negotiated.

CRAM, DONALD JAMES (1919–2001). Awarded the Nobel Prize for chemistry, together with Jean-Marie Lehn, and Charles J. Pedersen, in 1987 for work in elucidating mechanisms of molecular recognition, which are fundamental to enzymic catalysis, regulation, and transport. He also studied three-dimensional cyclic compounds that maintained a rigid structure, accepting substrates in a structurally preorganized cavity. Cram called these compounds cavitands, while Lehn named them cryptands. Cram received his doctorate from Harvard University in 1947. See also **Cavitand**.

CRAMÉR-RAO INEQUALITY. In statistics, an inequality giving a lower bound to the sampling variance of an estimator. If t is an estimator of a parameter θ in a frequency function f and the bias is defined as

$$b(\theta) = E(t) - \theta$$

where E denotes expectation, then the inequality states that

$$\text{var } t \geq E\left\{\frac{\left(1 + \dfrac{\partial b}{\partial e}\right)^2}{\left(\dfrac{\partial \log f}{\partial \theta}\right)^2}\right\}$$

CRAMER RULE. Let

$$a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n = y_1$$
$$a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n = y_2$$
$$a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n = y_n$$

be n linear equations in n unknowns with nonvanishing determinant $D = \det\{a_{ij}\}$. Let D_i denote the determinant of the matrix obtained by replacing the ith column of $\{a_{ij}\}$ by the column $y_1, y_2, \cdots, y_n$. Then Cramer's rule gives the solution of the above equations in the form $x_i = D_i/D$, $i = 1, 2, \ldots, n$. The rule is of theoretical importance, but of little value in computing practice.

CRANE FLY *(Insecta, Diptera)*. Insects, *Tipulidae* (Daddy long-legs), which resemble mosquitoes in form but are usually much larger. They have a V-shaped groove across the thorax and have no scales on the wings.

The larvae of some species live in the ground and are sometimes injurious to the roots of grasses and grains. These larvae are called meadow maggots or leather jackets. They come to the surface at times and can be destroyed by the use of poison baits.

CRANKSHAFT. A crank is a bent arm that moves with rotary motion about its unbent end. In order to provide a support for this rotation the crank is mounted on a crankshaft. The crank and crankshaft form one of the important basic units of mechanism. This is an efficient way of transforming rotary to reciprocating motion, or vice versa. The crank alone does not accomplish this, but in conjunction with the connecting rod and slider, it forms the basis of many such important machines as engines, pumps, compressors, and a host of other mechanism. A simple crankshaft of the overhung type is readily made from an arm (or disk) and a crank pin which is set into it at some radial distance from a crankshaft, which is the center of rotation. This type is used where a crankshaft is to accommodate but one crank, and where the crankshaft-bearing surface is entirely on one side of the crank. Multiple cranks on the same crankshaft are obtained by fitting the crank pin between two crank arms, so that the connecting rod may swing freely without interference with the crankshaft. Multiple throw crankshafts are made by building up the crank pin between two cranks, and by machining from a single forged piece. It is the function of a crank to transmit the force at the crank pin into a torque at the crankshaft, the torque being equal to the component of crank pin pressure perpendicular to the crank radius multiplied by that radius. Since crank pin pressure is not always exactly perpendicular to crank radius, it follows that a crank may carry some compression or tension as well. It should not be loaded with bending by forces parallel to the crankshaft.

CRATER (Constellation). A small southern constellation located near Hydra.

CRATON. A part of the earth's crust which has attained stability and which has been little deformed for a prolonged period. The extensive central cratons of the continents (central stable regions) include both shields and platforms. Parts of the more mature Phanerozoic foldbelts have not achieved, or are approaching a cratonic condition. In terms of continental margins, a *cratonic margin* lies entirely on continental crust. Strictly speaking, they do not qualify as transition between continental and oceanic crust. They do, however, occupy large areas covered by seas. Cratonic margins also may contain thick sediment accumulations. See also **Ocean**.

CREEPER *(Aves, Passeriformes)*. Small insectivorous birds (Aves) that cling to the trunks of trees or cliffs in seeking food. They are found in the Northern Hemisphere and are represented in North America by the brown creeper, *Certhia familiaris*, sometimes called tree creeper. There are about five species of creepers in all, ranging from Nicaragua northward to Alaska and westward to Japan.

The brown creeper is dark brown with lighter brown on the lower half of the body. The basic brown coloration is spotted and striped with gray. The throat is white. The bill is slightly curved and slender and is especially shaped to pierce behind bark on trees. The tail is stiff and used as a brace. Often the nest will be jammed into a crevice behind scales of bark. The nest will be constructed of bits of bark, moss, or twigs. Often it will be from 20 to 40 feet (6 to 12 meters) above ground level.

The male feeds the female while she incubates the eggs. In some species, the male also helps with the incubation. The eggs hatch in about 21 days. They are white-spotted brown.

The short-tailed creeper (*C. brachydactyla*) is found in Asia, Africa, and parts of Europe. The high Himalayan mountain regions claim three species of creepers. These birds are larger, with a somewhat darker overall coloring. The bills are longer and the tails are striped. The Nepalese creeper (*C. familiaris nipalensis*) and the Sikkim creeper (*C. discolor*) are found at altitudes up to 12,000 feet (3,600 meters).

Usually the creepers are classified in the family *Certhiidae*, although some authorities believe that they should be grouped with the nuthatch family.

CREEP (Geology). The slow movement of soil and rock waste down a slope. This movement may be due to the combined influence of gravity, frost, and groundwater. Creep is a factor in soil erosion even on relatively flat slopes.

CREEP (Metals). This term usually is associated with the slow, plastic deformation of metals under constant load. Continued plastic deformation, where the applied force does not change, can result from two basic causes. (1) If a metal is deformed, as in tension, its cross section is correspondingly reduced. This raises the stress level in the material and, if the rate of this increase in stress exceeds the rate of strain hardening, creep occurs. (2) Plastic flow may be promoted by thermally activated softening processes occurring in the metal that counteract the mechanisms leading to strain hardening. Thus, thermal energy may aid dislocations in cutting through one another or in passing around inclusions. Thermal energy may also provide the means for dislocations of opposite sign to move toward each other so that they can recombine. This may eliminate dislocations entrapped in each other's force field, thereby allowing additional dislocations to move out from the sources and plastic deformation to continue.

Creep of metals at high temperatures is primarily controlled by thermally activated processes. Since there are many conceivable mechanisms, creep cannot be associated with a single activation energy. However, in a given temperature range, the creep rate may be controlled by a particular mechanism and the temperature dependence of the creep rate in this range will be related to a corresponding activation energy. Thus, several activation energies have been observed for creep in aluminum, each of which is controlling in a different temperature range. In general, the activation energy is larger the higher the temperature range in which it controls. The activation energy for creep of metals at very high temperatures (just below the melting point) often tends to be the same

as that for self-diffusion. This implies that vacancy motion or dislocation climb is very important in creep at extremely high temperatures.

From a practical point of view, creep becomes an important natural phenomenon when the temperature at which a metal is loaded lies above about 0.4 to 0.5 of its melting point on an absolute scale. In some metals such as zirconium, which undergo a solid state phase change, creep becomes an important effect above about one-half of the temperature of the phase transformation. In many metals such as steel, creep is almost non-existent at room temperatures if the metal is not loaded above its annealed yield strength. However, at 900 °F (482 °C) steel can creep readily at very small stresses, and equipment such as boilers and tubes for petroleum cracking stills, intended to operate at high temperatures for long periods of time, must be designed on the assumption that creep will occur. Alloy steels and other materials have been developed having much higher creep strengths than carbon steel.

Creep strength is the unit stress that will produce deformation at a specified rate at a specified temperature; for example, the creep strength of a certain 0.15% carbon open-hearth steel at 1000 °F (538 °C) is 6,100 pounds per square inch (415 atmospheres) for a rate of 0.01% elongation in 1,000 hours. Other values for this material are 6,900 pounds per square inch (469 atmospheres) for a rate of 0.1% and 7,800 pounds per square inch (531 atmospheres) for a rate of 1.0% elongation in 1,000 hours. Creep strength values can only be determined by long- time laboratory tests under carefully controlled conditions of temperature and loading.

CREOSOTE. See **Coal Tar** and Derivatives.

CREPUSCULAR RAYS. Literally "twilight rays," these alternating dark and light bands (shadows and light scattered from sunbeams, respectively) seem to diverge fanlike from the sun's position during twilight. Also called *shadow bands.*

This apparent divergence of parallel sunlight is an artifact of linear perspective. Crepuscular rays may appear as 1) shadows cast across the purple light by high, distant cloud tops or 2) shadows next to light scattered from sunbeams by haze in the lower atmosphere. Sunbeams seen during the day are sometimes called crepuscular rays, even though they are observed outside twilight.

CREST CLOUD. See **Clouds and Cloud Formation**.

CRETACEOUS PERIOD. The last major division in the Mesozoic Era of the geologic time-scale. Type locality, chalk (creta) cliffs of the English Channel. The period was named by A. d'Halloy in 1822. In 1877, Hill proposed that the Lower Cretaceous be erected as a separate system, which he called the Comanchean. The Comanchean period began about 135 million years ago and lasted about 25 million years. The Cretaceous period began about 110 million years ago, and lasted about 50 million years. The greatest thicknesses of Cretaceous strata in the United States occur in the Rocky Mountain region and in California. During the Cretaceous Period there was also an extensive overflow of the waters of the Gulf of Mexico toward the southern interior of the United States, depositing there a great series of overlapping sediments. This is the type region of the Lower Cretaceous or Comanchean. While the Atlantic and Gulf continental margins were invaded by the Cretaceous Sea, the region of the Appalachian geosyncline had been reduced to peneplain, which may have been overlapped by marine sediments. In the Great Plains region were deposited freshwater shales and sandstones with local swampy areas in which were formed numerous lignites, subsequently altered to bituminous coal. The Middle Cretaceous saw a great marine invasion of western North America from the Gulf of Mexico to the Arctic Ocean. Deposits of Cretaceous Age are well represented in central and western Europe, with fairly continuous marine deposition throughout the entire period. Cretaceous deposits occur in South America, especially in Brazil. As further evidence that there was widespread invasion of the continents by oceanic waters during this period, sediments occur in southwestern Asia, China, Himalayas, Japan, Siberia and Africa. Important mineral resources are of Cretaceous Age. In the United States the Cretaceous formations contain numerous important aquifers which underlie great semi-arid areas. Bituminous coal beds average value occur in Alaska, Australia, British Columbia and Germany. Important oil pools occur in the Gulf region. The Cretaceous clays of the eastern United States are extensively used in the manufacture of china and building materials. The sulfide copper ores of Butte, Montana, occur in igneous rocks of Cretaceous and Early Tertiary age. Lower Cretaceous plants and animals were only slightly different from those of Jurassic time. Ferns, cycads, ginkgoales and conifers still predominated, and the principal marine invertebrates were ammonites and belemnites. During the Cretaceous there was a great expansion of the pelecypods, gastropods, and the modern types of fishes. The Mesozoic reptiles had reached their climax in the early Cretaceous and, except for a few large and bizarre forms, were on their way to extinction. The most remarkable types were Triceratops (horned dinosaur), Tyrannosaurus (tyrant dinosaur), Tylosaurus (marine lizard), and Pteranodon (crested pterodactyl, or flying reptile). Since uppermost marine Cretaceous does not occur in North America, there appears to have been a pronounced period of uplift and erosion, accompanied by mountain building, with the combined growth of the Cordilleran ranges. This period of diastrophism, which closed the Mesozoic Era in the Western Hemisphere, is called the *Laramide Revolution*. See Fig. 1.

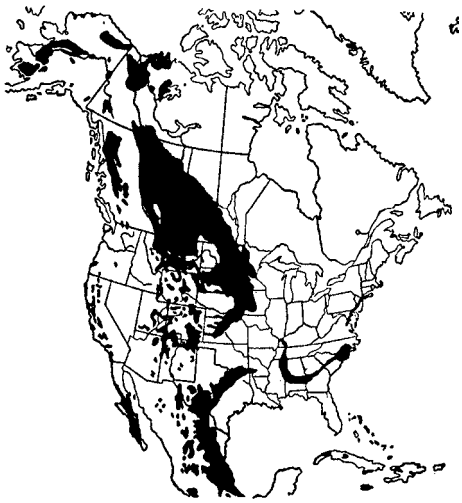

Fig. 1. North America, showing the surface distribution (areas of outcrops) of Cretaceous strata. The large and small areas in the western interior of the continent largely represent Upper Cretaceous deposits.

CREUTZFELDT-JAKOB DISEASE AND RELATED DISEASES. Over the last few decades, a few apparently related diseases that affect and ultimately destroy brain functions have been identified among humans and various other animal populations. Although there have been a few epidemics, these diseases normally affect only one or two individuals per 1 million population. At this point of understanding, the diseases could generally be described by the term *spongiform encephalopathy*, a condition that is displayed at autopsy. The diseases have a pattern of causing progressive dementia and ultimately death. Although, at one time, considered noninfectious, recent studies have proved that at least some of these diseases are transmissible.

Because of late onset of some of these diseases, for a number of years the causative agent(s) were considered to be "slow viruses," a term no longer in popular usage. In fact, as of 1993, the causative agent has not been positively identified. Contemporarily, the agent usually is identified as a *prion*, which is defined in the article on **Bacteria** as an infectious pathogen that does not fully fall within the classical definition of bacteria, fungi, parasites, viroids, and viruses. However, there are opinions among some professionals that the agent is a very poorly understood virus.

The mystery of the pathogen derives from the inability thus far to observe the agent by electron microscopy, from the fact that the agent causes no immune response, and that it can withstand high temperatures and ultraviolet and other forms of radiation far beyond those conditions that would destroy known bacteria and microorganisms. Thus, until more research can be conducted, the agent is referred to as a *prion.*

Kuru

This disease was first described in 1957 among the Fore tribe and adjacent people with whom they intermarry in the eastern highlands of New Guinea. At the time, the disease was epidemic and chiefly affected children of both

sexes and adult females. Initially, adult males were rarely affected, but there has been a rise in the number of men who have died of the disease.

The relationship of kuru to cannibalism has been well documented. Before the suppression of cannibalism in the 1950s, it was customary for women and children to eat the brains of their dead kinfolk for gastronomic reasons and to show respect for the dead. It was rare for the men to partake of these feasts. The incubation period of the disease is about twenty years after consumption of the infected material. The onset is insidious with ataxia which progresses over 3 to 6 months to a stumbling walk and a destructive tremor. Choreiform and wild athetotic movements occur and there are pronounced emotional changes and easily provoked inordinate laughter. Later, walking becomes impossible, and dysarthria and dysphagia occur. Death eventuates between 3 and 24 months. At autopsy, there is a marked degeneration in focal areas in the cerebral cortex, but most changes are seen in the shrunken cerebellum.

Early observations of kuru indicated that the disease was provoked by consumption of human brain tissue and that the disease was not transmissible from one infected person to the next. However, D. Carleton Gajdusek (U.S. National Institute of Neurological and Communicative Disorders and Stroke) was awarded a Nobel Prize (Medicine) in 1976 for establishing that kuru can be transmitted to chimpanzees.

Scrapie

For several decades, a disease of sheep and goats known as scrapie affects these animals in a way that kuru affects humans as just described. As of the 1990s it had not been proven that scrapie can be transmitted from sheep to humans, but growing concern that this may be possible was been precipitated by a high incidence of fatal dementia of unknown cause that occurred in Slovakia, particularly in the regions of Orava (on the Polish border) and Lucenec (on the Hungarian border). Since 1976, 22 cases have been diagnosed in Orava, 12 of the cases discovered in the early 1990s. At Lucenec, another 19 cases have been located. The disorder, sometimes termed keru, currently is professionally diagnosed as Creutzfeldt-Jakob disease. Further research may show that these variously named diseases are different manifestations of a single prion disease.

More recently, in the United Kingdom, cattle were infected with a similar disease. Temporarily, this was identified simply as "mad cow disease." As a precautionary measure, 15,000 cattle have been destroyed since 1986.

Creutzfeldt-Jakob Disease

This disease was not made known to the medical profession until described by Hans G. Cruetzfeldt and Alfons M. Jakob, both German psychiatrists, in the mid-1960s. A striking similarity to kuru was identified. Creutzfeldt-Jakob disease (CJD) meets exceptionally well the definition of a subacute spongiform encephalopathy. The brain pathology shows neuronal degeneration, astrocytic proliferation, and the presence of minute vesicles, but there is no trace of inflammation or infectious disease.

This disease can occur in both sexes, most commonly with the ages of 50–65 years with a range from 32 years to old age. Occasional cases have been seen in the second and third decades.

In about 90% of these cases, the disease runs its fatal course in a year; sometimes within a month. The onset is often abrupt, although sometimes, prodromal symptoms of depression, lack of interest, and dizziness have been described. The initial signs are usually identifiable as being due to organic brain disease and the onset of intellectual deterioration may be misinterpreted as primary psychiatric disease. Advance is rapid, speech is lost and swallowing becomes difficult. The limbs adopt a rigid, flexed, posture and there is a rapid repetitive contraction of muscles in the face, trunk, or limbs. Even when the patient is completely speechless and helpless, the eyes may remain open and the level of consciousness is indeterminate.

In the remaining 10% of cases, the onset is more gradual; cortical blindness and myoclonus are less common. The dominant features are dementia, increased limb tone, and muscular wasting. The pathological findings are the same in both types of cases, but these chronic patients may survive for several years. A mild degree of cerebral atrophy can be detected by computerized axial tomography (CAT) scan and, in subacute cases, the electroencephalogram (EEG) nearly always shows periodic discharges of stereotyped spike or spike and slow wave activity.

The incidence of CJD is not fully known, and although it probably occurs worldwide, in most countries not more than one to two case per million population is seen. An unusually high cluster incidence has been seen in Israelis of Libyan origin.

Once considered nontransmissible, CJD, closely related to kuru, is now considered transmissible. Y. Tomai (Tokyo Metropolitan Institute for Neurosciences) http://www.tomai.ac.fpl and colleagues, in August 1992, reported findings of the transmissible agent in samples from a pregnant woman with CJD. (The woman died 3 years later and at autopsy her brain weighed only 800 grams.) Examination revealed a severe loss of nerve cells, a spongy state, and demyelination in both the cerebrum and the cerebellum. The fluid samples taken from the patient were injected intracerebrally into BALB/c mice. The tissue from the patient's brain was found to be infective. However, no signs developed in control mice inoculated with healthy mother's milk.

The disease has been accidentally transmitted by corneal implant and by incompletely sterilized intracerebral electrodes. It appears that transmission can only take place if tissue from a donor is implanted into the host. Special care must be taken when handling tissues from known or suspected cases of CJD, but otherwise the patient can be nursed normally.

Probable Genetic Connection to CJD. It has been established for a number of years that CJD occurs at a frequency 100 times that of the 1 to 2 cases per 1 million population in Libyan Jews. In early 1991 Hsiao and a group of investigators (under sponsorship of the Israeli Ministry of Health, the American Health Assistance Foundation, and the National Institutes of Health) published a study of this higher incidence of CJD. For a number of years this susceptibility to CJD was thought by some to be the result of culinary practices (for example, consumption of lightly cooked sheep brain as well as sheep eyeballs).

But, since other Sephardic Jews in the Middle East and North Africa also have similar culinary habits (but no high incidence of CJD), the culinary causation did not appear logical. This precipitated the aforementioned study. The details of the study are too detailed and complex to include here, but the study concludes: "The codon 200 lysine mutation of the prion-protein gene is consistently present among Libyan Jews with CJD, strongly supporting a genetic pathogenesis of their illness. The similarity of the clinical course of the patient homozygous for this mutation and the patients heterozygous for it argues that familial CJD is a true dominant disorder." See Table 1. See also **Bovine Spongiform Encephalopathy (BSE)**.

TABLE 1. SUMMARY OF CJD-LIKE DISEASES[1]

Contemporary Name	Affects
Creutzfeldt-Jakob Disease	Humans
Kuru	Humans
Gerstmann-Sträussler Syndrome	Humans
Bovine Spongiform Encephalopathy or "mad cow" disease	Cattle
Scrapie	Sheep
Transmissible Mink Encephalopathy	Mink
Chronic Wasting Disease with Spongiform Encephalopathy	Captive Rocky Mountain elk and mule deer
Spongiform Encephalopathy	Nyala (antelopes), gemsbock, and the domestic cat

[1]As arranged by Beardsley.

CREVASSE. 1. A crack or open fissure in a glacier. 2. A break in the levee of an old-age, meandering stream, often leading to disastrous floods, as in the case of the lower stretches of the Mississippi River.

CRICKET *(Insecta, Orthoptera).* Insects related to the katydids and grasshoppers and, like some of these forms, well known for their resonant singing. The true crickets constitute a family (*Gryllidae*) which contains the common or field crickets and in addition several other forms more or less different in appearance. The field crickets are black or brown species, some of which enter houses. Tree crickets are usually green with broad transparent wings. They frequent trees and shrubs. Mole crickets are thick-bodied brown insects whose forelegs are strongly developed for burrowing. In addition to these and a few other forms of crickets several insects belonging with the katydids among the long-horned grasshoppers bear this name. They are the cave or camel crickets, the sand cricket, and the Mormon cricket. See Fig. 1.

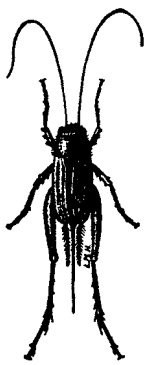

Fig. 1. Cricket.

Crickets, like grasshoppers, beetles, cicadas, and cockroaches, are among the most ancient insect inhabitants of the earth. There are about 900 known species. The average cricket is about $\frac{1}{2}$ to 1 inch (12 to 15 millimeters) long. Its thighs are large in proportion to the rest of the body. The tarsi is in three segments. Some crickets possess tympanic membranes (on the order of the human eardrum) which are located in cavities on the front legs. Movement of a leg enables the insect to determine the direction of sound.

The male cricket produces a chirruping sound by rubbing together especially modified parts of its forewings. In many areas, the cricket appears on or about June 15 in the Northern Hemisphere and announces its presence with the loud "song" of the males, usually at dusk. Hoy and Paul have made a study of genetic control of song specificity in crickets which is reported in *Science*, **180** (4081), 82–83 (1973). The calling song of male field crickets is composed of stereotyped rhythmic pulse intervals, which are predictable expressions of genotype. Females identify conspecific males by their song. Two species of crickets were found to exhibit species-specific song preference, and hybrids between them preferred hybrid calls over either parental call. These results imply genetic control of song reception as well as transmission. The mating of tree crickets is well described by D.H. Funk, *Sci. Amer.*, **50** (August 1989).

As reported by Franz Huber and John Thorson, these investigators have made extensive studies of cricket auditory communication. They have been investigating the female cricket's ability to recognize the male's calling song and to seek out the source of the song, which can be used as a key to how nervous system activity underlies animal behavior. Using modern electronic and physiological methods, the investigators have been probing how the neurons, or nerve cells, in the female's central nervous system distinguish the male's song from other songs and sounds. Given the curious arrangement of the cricket's auditory receptors (the cricket's ears are situated below the knees), how does the female determine the direction of the song? More than a dozen laboratories around the world are attempting to find the answers. As pointed out by the authors ["Cricket Auditory Communication," *Sci. Amer.*, **253**(6), 60–68 (December 1985)], a central aspect of the neurosciences is the attempt to explain the behavior of an animal in terms of the operation and interactions of individual neurons. Such work frequently is done with invertebrates because of their stereotyped behavior, the relative paucity of their nerve cells, and the fact that many of the largest neurons can be identified readily in all members of a species. Thus far, the greatest successes have come on the output, or motor, side of neutronal organization. The investigators have concentrated their efforts on European field crickets (*Gyrrlus campestris* and *G. bimaculatus*).

The *field cricket* (*Gryllus assimilis*, Fabricius) is distributed throughout the United States, southern Canada, and a large part of South America. The insect is particularly damaging to cotton in California and the Gulf states. This is caused by the insect cutting off seedling plants just above ground level. They devour alfalfa and grain seeds in the Great Plains States and even attack grain after it has been harvested. There is one generation per year, usually wintering over in the egg stage. However, generations of different broods overlap and thus adults may be present from spring to fall.

The *Mormon cricket* (*Anabrus simplex*, Haldeman) and the *coulee cricket* (*Peranabrus scabricollis*, Thomas) are not true crickets, but are closely related to katydids and longhorned grasshoppers. One of the first recorded outbreaks of an infestation by the Mormon cricket occurred in 1848 in the Great Salt Lake basin. This invasion was spectacularly terminated by many flocks of gulls to which the settlers later erected a monument. This cricket is found west of the Missouri River, but is most destructive in the Pacific Northwest, Nevada, Utah, Idaho, Montana, Wyoming, and Colorado. The coulee cricket has caused major damage in Montana and Washington.

These crickets attack a host of vegetable and fruit crops. Both species are cannibalistic, consuming dung and dead animals. Advantage of the fact that these insects do not fly is taken in constructing barriers, ditches, etc. to prevent their migration from one area to the next. A film of petroleum distillate on an irrigation ditch can be effective.

The *snowy tree cricket* (*Oecanthus niveus*, De Geer) and closely related tree crickets damage fruit trees and bushes. The insects drill small holes in small twigs and brambles. A rather large, pale-yellow egg (about $\frac{1}{8}$-inch long; 3 millimeters) is deposited in each hole. There may be as many as several dozen such punctures in just a few inches. These puncture wounds serve as sites for fungus and other infection. The adults puncture and eat ripe fruit, rendering it unfit for market. The tree crickets are active on apple, blackberry, cherry, loganberry, peach, plum, prune, and raspberry.

CRICK, FRANCIS HARRY COMPTON (1916-2004). Francis Crick was an English scientist who, with James D. Watson, discovered the double helical structure of DNA.

Francis Crick was born in 1916, in Northampton, England, into a middle-class family. Neither parent had an academic background but Crick's intelligence and keen sense of curiosity were recognized early and encouraged — he was carrying out experiments at home by age ten. He studied physics at University College London, and began research there. However, this was interrupted by World War II and in 1940 Crick began wartime research for the British Admiralty.

After the war, Crick came to realize that biology–especially what we now call molecular biology and neurobiology–was what interested him. The Medical Research Council (MRC) http://www.mrc.ac.uk/index.htm, provided him with a studentship to carry out his first biological research, at the Strangeways Laboratory in Cambridge (1947–1949). Here, he attempted to determine some properties of cytoplasm by using magnets to move small particles of magnetite taken up by cells in tissue culture. After two years at Strangeways, Kenneth Mellanby, Secretary of the MRC, arranged for Crick to join a new MRC unit, headed by Nobel Laureate Sir Lawrence Bragg, at the Cavendish Laboratory in Cambridge. The unit was to study protein structure using X-ray diffraction and Crick's new colleagues included Max Perutz and John Kendrew. See also **Kendrew, John Cowdery (1917–1997**; and **Perutz, Max Ferdinand (1914–2002)**.

At this time, although 33 years old, Crick was still a graduate student with no record of success. He was a lively addition to a small research group and soon became notorious for his constant and voluble talking. He did some useful work–for example, publishing an important theoretical paper on Fourier analysis with William Cochran (1952)–but Sir Lawrence Bragg regarded him at this time as a nuisance. Then in October 1951, a young American scientist, James D. Watson, arrived at the Cavendish. They found that they had much in common, not least a passionate desire to determine the physical nature of the gene. See also **Watson, James Dewey (1928–Present)**.

By this time, it seemed possible that genes were made of the deoxyribonucleic acid (DNA), rather than the protein, found in chromosomes so their goal was to determine the structure of DNA. Watson and Crick took a model-building approach, following the example set by Linus Pauling in his discovery of the α-helix of protein molecules (1951). Maurice Wilkins, Crick's friend at King's College London, was carrying out X-ray crystallography of DNA, although the project had been taken over by Rosalind Franklin. In February 1953, based on data from a variety of sources, including a beautiful diffraction pattern obtained by Franklin, Watson and Crick developed the double helical model of DNA that has become an icon representing modern science. See also **Franklin, Rosalind Elsie (1920–1958)**; and **Wilkins, Maurice Hugh Frederick (1916–2004)**.

Crick completed his PhD in 1953, and while Watson and he produced an important paper on the general structure of viruses in 1956, both turned to working out the implications of the double helix. The next goals were to understand how the order of nucleotide along the DNA molecule represented the order of amino acids along a protein molecule (the "coding problem"), and how the protein synthesizing machinery of the cell used the order of the nucleotides to make proteins. George Gamow was the first to tackle the coding problem (1954) and, although his ideas were wrong–he disregarded several basic chemical facts–he showed Watson and Crick that the problem might be approached theoretically. Watson became more interested in the role of a second nucleic acid, ribonucleic acid (RNA), but Crick worked on the coding problem, contributing many ideas and writing a series of very elegant papers.

Most notable of these ideas were the "Adaptor Hypothesis" and the "Central Dogma." The former was written in 1955 for private circulation but not published until 1958. Crick suggested that there were small RNA molecules that would act as intermediaries between nucleic acids and amino acids. In fact, these adaptor molecules had already been discovered, but not recognized by the biochemists Paul Zamecnik and Mahlon Hoagland. At the same time, Crick enunciated the Central Dogma. Watson had pointed out that information flows from DNA to RNA to protein but Crick extended this with the notion that this flow is one way: "once information has passed into protein it cannot get out again." Watson's idea had to be revised later when it was found that an RNA molecule can be used as a substrate for synthesizing a DNA molecule, but Crick's insight that information in a protein molecule cannot be transmitted to a nucleic acid still holds true.

Crick and his colleagues (1957) devised a genetic code that was very seductive in its numerological elegance but, unfortunately, proved to be completely wrong. On the other hand, in 1961, Crick, Barnett and Brenner demonstrated experimentally that three nucleotides coded for each amino acid and the study has become a classic of molecular genetics. But the coding problem was not solved by theoretical analysis. Instead, the solution came through the biochemical experiments of Marshall Nirenberg and Gobind Kohrana who in 1961 showed that an amino acid was coded for by three nucleotides–a triplet or codon. Crick's final contribution to the genetic code was his "wobble hypothesis" which explained why the third position of a triplet was variable (1966). See also **Nirenberg, Marshall Warren (1927–Present)**.

With the determination of the genetic code and the working out in broad outline of the mechanism of protein synthesis, it seemed to some leading molecular biologists that all big ideas had been discovered and mopping up was all that remained. Crick, Sydney Brenner and Seymour Benzer were amongst those who turned to other biological pastures. Crick worked on the role of chemical gradients in development but this proved experimentally intractable and he contributed to work on the structure of chromosomes. In 1981, Crick published an interesting and controversial book in which he suggested that the origin of life could be accounted for by "directed panspermia," microorganisms having been sent here from elsewhere in the universe. See also **Brenner, Sydney (1927–Present)**.

In 1976, Crick moved to the Salk Institute in La Jolla as the Kieckhefer Professor and has remained there ever since. His research has been in cognitive science, especially the mammalian visual system and the problem of consciousness.

Francis Crick has been awarded many honors. He was made a Fellow of the Royal Society in 1959, being awarded the Royal (1972) and Copley (1975) Medals. He was made a Foreign Associate of the National Academy of Sciences, USA, in 1969. Crick shared with James Watson and Maurice Wilkins the Lasker Award (1960) and the Nobel Prize for Physiology or Medicine (1962). In 1992, he received the Order of Merit from Her Majesty Queen Elizabeth.

CRINOIDEA. The sea lilies, feather stars, and basket stars, a class of the phylum Echinodermata. There are now only a few hundred species of these animals although several thousand fossil species are known.

The crinoids are distinguished from the starfishes and other echinoderms by the following characteristics: (1) The body consists of a disk, arms, and a stalk. (2) The mouth and anus are both directed upward. (3) The arms bear small lateral branches and in many species fork repeatedly.

Most of the living species lose the stalk when mature and become free-swimming. These forms, known as comatulids, are found in shallower waters of the ocean, where they swim or creep by means of the arms. The stalked species are found in deep water.

The classification of crinoids is of little interest save to specialists. Many families are recognized and they are generally grouped into orders, which include a primitive attached form, the stalked crinoids, and the free species.

CRIPPLED LEAPFROG TEST. In computer operations, a modified leapfrog test in which tests are repeated from a single set of storage locations and do not leap to another set of storage locations.

CRITICAL COMPOSITION. Systems consisting of two liquid layers that are formed by the equilibrium between two partly miscible liquids,

frequently have a consolute temperature or a critical solution temperature, beyond which the two liquids are miscible in all proportions. At this temperature, the phase boundary disappears, and the two liquid layers merge into one. The composition of the mixture at that point is called the critical composition. There is, in some cases, a lower consolute temperature as well as an upper consolute temperature.

CRITICAL CONCENTRATION. When two immiscible liquids are heated in contact with each other their mutual solubility is usually increased until, at the critical solution temperature, they become consolute. The composition of the two solutions immediately before they become consolute is termed the critical concentration. See also **Critical Solution Temperature**.

CRITICAL DENSITY. The density of a substance which is at its critical temperature and critical pressure.

CRITICAL FREQUENCY. 1. A wave radiated from the antenna of a radio transmitter spreads in various directions, the exact nature of its spread being determined by the directional characteristics of the antenna. The part that travels toward the outer atmosphere goes into the ionosphere where it acts upon the ionized particles, principally electrons, which absorb energy and re-radiate it. The net result of this action is an effective change of the index of refraction of the medium through which the wave is traveling. This causes the wave to be bent back toward the earth, the extent of the bending varying with the index. This causes radio waves to be returned to the earth to give reception at points very remote from the transmitter. However, this change of index of refraction varies with frequency in such a manner that the waves are bent less and less as the frequency is raised. A critical frequency is finally reached where the wave is not bent enough to return to the earth, even for the most glancing angle of incidence which it is possible to obtain. As the frequency of the signal is progressively raised, the critical frequencies for the various layers of the ionosphere are reached in turn, the wave penetrating each at its critical frequency and being refracted back to the earth by the next layer, until, finally, all layers are penetrated, and there is no returning signal. This occurs in the vicinity of 40 megacycles.

2. In a usage closely related to that in the first definition the critical frequency of a magnetohydrodynamic wave component is that frequency at which it is reflected by, and above which it penetrates through, an ionized medium (plasma) at vertical incidence.

CRITICAL LEVEL OF ESCAPE. That level, in the atmosphere, at which a particle moving rapidly upwards will have a probability of 1/e, where e is base of natural logarithm, of colliding with another particle on its way out of the atmosphere. It is also the level at which the horizontal mean free path of atmospheric particle equals the scale height of the atmosphere. The critical level of escape is the base of the exosphere. Also called *level of escape*, or *critical level*. Estimates of the height of the critical level of escape range from about 500 to 1000 kilometers. This large range of estimated values is due primarily to the general uncertainty about the temperature distribution in the ionosphere.

CRITICAL MACH NUMBER. The free-stream Mach number at which a local Mach number of 1.0 is attained at any point on the body under consideration. For example, an airplane traveling at a Mach number of 0.8 with respect to the undisturbed flow might attain Mach number of 1 in the flow about the wing; the critical Mach number would thus be 0.8.

CRITICAL MASS. The amount of concentrated fissionable material that can just support a self-sustaining fission reaction.

CRITICAL OPALESCENCE. The phenomenon sometimes produced when a homogeneous solution of two liquids at its critical composition is cooled from a temperature above its consolute temperature to one below that temperature. This phenomenon consists of a bluish haze, which is believed to be due to the scattering of light brought about by local variations of density within the liquid.

CRITICAL POINT. 1. A point where two phases, which are continually approximating each other, become identical and form but one phase. With a liquid in equilibrium with its vapor, the critical point is such a combination of temperature and pressure that the specific volumes of the liquid and its vapor are identical, and there is no distinction between the two states. 2. The critical solution point is such a combination of temperature and pressure that two otherwise partially miscible liquids become consolute.

To consider in detail the critical point as defined in (1), examine Fig. 1, which shows the family of isotherms of a pure substance in the fluid range (liquid or gas) such for example as shown in the figure for carbon dioxide.

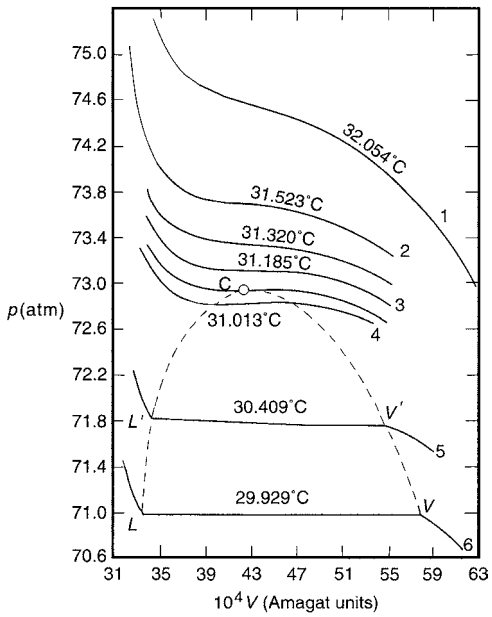

Fig. 1. Isotherms of carbon dioxide in the neighborhood of the critical point.

At sufficiently high temperatures each isotherm is a continuous curve, but at low temperatures the isotherm consists of three portions. The first section of the curve at high pressures corresponds to the liquid state, while that at low pressures refers to the gaseous state. These two curves are joined by a horizontal line, corresponding to the simultaneous presence of two phases, liquid and gas.

The isotherm between those numbered 3 and 4 in the figure represents the transition between isotherms corresponding to the gas phase only, and those including a horizontal portion corresponding to a liquid-gas equilibrium. In this isotherm the horizontal line has contracted to a single point of inflection C. This is the critical point characterized by the relations

$$\left(\frac{\partial p}{\partial V}\right)_{T_c} = 0; \quad \left(\frac{\partial^2 p}{\partial V^2}\right)_{T_c} = 0; \quad \left(\frac{\partial^3 p}{\partial V^3}\right)_{T_c} < 0.$$

The curve $LL'C$ gives the molar volume of the liquid. Similarly $VV'C$ gives the molar volume of the gas.

At the critical point the molar volumes of the liquid and of the gas become equal. In general a critical state is characterized by the fact that the two coexistent phases (here the liquid and the vapor) are identical.

The curve $VV'CL'L$ is called the *saturation curve*.

The experimental data do not indicate the existence of a critical point for the liquid-solid transition.

Above the critical point the substance can no longer exist in the liquid state. The critical temperature is thus the highest temperature at which the liquid and vapor can coexist.

Ternary Critical Point. The point where, upon adding a mutual solvent to two partially miscible liquids (as adding alcohol to ether and water), the two solutions become consolute and one phase results.

CRITICAL POTENTIAL. In atomic physics, the critical potential is used in general as a measure of the amount of energy necessary to raise an electron from a lower to a higher energy level. The term "potential" is used because the quantity of energy is measured by means of electrons accelerated by application of a known potential, the energy of the electrons being given by the product of the accelerating potential and the electronic charge.

Two kinds of critical potentials are the ionization potentials and the resonance potentials. The ionization potential represents the work necessary to remove an electron from a normal atom wherein the electron may be supposed to be in its lowest level, to an infinite distance, so that a positively charged ion results. The resonance potential is a measure of the work required to raise an electron from the lowest level to any other level; therefore, there are first, second, etc., resonance potentials, corresponding to the transfer of an electron from the lowest level to the next level, to the next-but-one level, etc.

CRITICAL PRESSURE. 1. In rocketry, the pressure in the nozzle throat for which the isentropic weight flow rate is a maximum.

2. The pressure of a gas at critical point, which is the highest pressure under which a liquid can exist in equilibrium with its vapor.

CRITICAL REACTOR. The steady-state condition of a reactor in which the neutron fission process is self-sustaining without the aid of external neutron sources. A critical reactor has a criticality factor of one ($k_e = 1$).

CRITICAL REGION. The region in the diagram of state of a substance in the neighborhood of the critical point.

CRITICAL REGION (Statistics). In the statistical theory of hypothesis testing, a region in the sample space (i.e., the space of all possible samples) such that, if a point falls within it, the hypothesis is rejected. The region is, of course, determined by the hypothesis, the nature of the probability distribution of the variables and the degree of assurance or confidence required to decide on rejection.

CRITICAL RESOLVED SHEAR STRESS. The shear stress resolved on a slip plane and in the slip direction that just causes a metal single crystal to undergo slip. Tables 1 and 2 give the critical resolved shear stresses for some typical metals.

The ready occurrence of slip along a crystallographic plane (see **Crystal**) gives rise to the small magnitudes of these stresses which are 10^3 to 10^4 times smaller than the theoretical shear strength of the same crystals. This discrepancy between theoretical and observed shear strengths of single crystals was responsible for the original postulation of dislocations.

Most determinations of the critical resolved shear stress are made using crystals deformed in tension. In this case, the Schmid resolved shear stress equation

$$S_s = S_n \cos\phi \cos\lambda$$

may be used, where S_s is the shear stress resolved on the slip plane and in the slip direction, S_n is the applied tensile stress, and ϕ and λ are the angles between the crystal tensile axis and the slip plane normal and slip direction, respectively. In a given set of previously undeformed crystals of the same composition, tested in tension at the same temperature that slip on the same crystallographic plane, it has been observed that the shear stress, determined with the aid of the above equation, is remarkably constant. It is thus apparent that the critical resolved shear stress is independent of crystal orientation. It does depend on the temperature and increases with decreasing temperature, as may be seen in part (a) of Fig. 1. The critical resolved shear stress also depends on the composition of the crystal and decreases with increased metal purity, as may be seen in the second figure for the case of silver and copper crystals (part (b) of figure). Any plastic deformation, because of work hardening effects, will increase the critical resolved shear stress.

TABLE 1. CRITICAL RESOLVED SHEAR STRESSES FOR FACE-CENTERED CUBIC METALS

Metal	Purity	Slip System	Critical Resolved Shear Stress (Psi)	kPa
Cu	99.999	{111}⟨110⟩	92	634
Ag	99.999	{111}⟨110⟩	54	372
Au	99.99	{111}⟨110⟩	132	910
Al	99.996	{111}⟨110⟩	148	1020

TABLE 2. CRITICAL RESOLVED SHEAR STRESS FOR BASAL SLIP

Metal	Purity	Slip System	Critical Resolved Shear Stress (Psi)	kPa
Zinc	99.999	{0001}⟨1120⟩	26	179
Cadmium	99.996	{0001}⟨1120⟩	82	565
Magnesium	99.95	{0001}⟨1120⟩	63	434

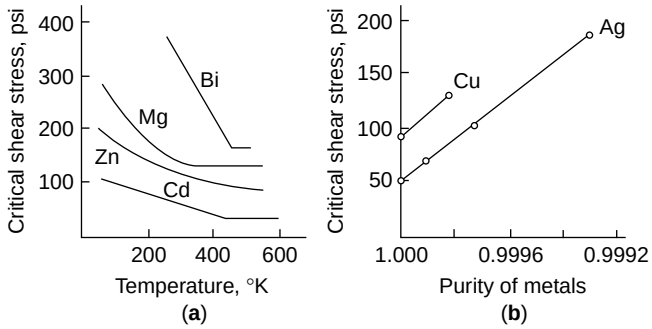

Fig. 1. (**a**) Effect of temperature on the critical shear stress. The data on which these curves are based predate Table 2. The higher critical stresses in this case correspond to crystals of lower purity, (**b**) Variations of the critical resolved shear stress with purity of the metal.

CRITICAL SOLUTION TEMPERATURE. For two partially miscible liquids, the compositions of the two conjugate solutions approach each other with increasing temperature. At the critical solution temperature the two solutions have identical compositions and form one layer.

CRITICAL SPEED. Any body having weight and "springiness" has one or more natural frequencies at which it can vibrate. If forces are applied to the body at any of these natural frequencies a resonance condition will build up, and the amplitude of motion will become quite large. Since a machinery shaft has weight and deflects under load, it has several natural frequencies. It is difficult to balance a shaft perfectly, so that during rotation centrifugal forces are set up within it that act on the shaft at the same frequency as the shaft rotates. If this impressed frequency coincides with a natural frequency of the shaft resonance occurs. This speed of rotation is then known as a critical speed.

Resonance is an undesirable condition as it may cause rubbing of parts and creates high shaft stresses. Consequently the running speed is kept at least 20% away from the critical speed. Since the shaft has a number of natural frequencies it also has a number of critical speeds. For most actual machinery shafts only the first or second critical speed is of importance.

CRITICAL TEMPERATURE. 1. This term is most commonly used to denote the maximum temperature at which a gas (or vapor) may be liquefied by application of pressure alone. Above this temperature the substance exists only as a gas. 2. The critical temperature of a superconducting transition takes place in zero magnetic field.

CRITICAL VELOCITY OF FLOW. If above a certain velocity of flow the nature of the flow changes qualitatively, the velocity is critical for the particular flow system. The criterion is always better expressed as a critical Reynolds number, Mach number, Froude number, or whatever the appropriate nondimensional parameter may be. See also **Turbulent Flow**.

CRITICAL VOLUME. The volume occupied by unit mass, commonly one mole, of a substance at its critical temperature and critical pressure.

CROAKERS *(Osteichthyes)*. Of the order *Percomorphi*, suborder *Percoidea*, and family *Sciaenidae*, croakers are fish named because of the sounds they produce. Sound is caused voluntarily by strong muscles, which are caused to vibrate much as a string instrument. The air bladder acts as a reasonating chamber. Although not fully understood, it is believed that

because of the correlation of this noise-making with the spawning season and because it also varies from day to night, the croaking is associated with the mating process. There are somewhat over 150 species in the croaker family. Most species prefer shallow water, are usually carnivorous, and habituate both tropical and temperate waters. Several species can adapt to brackish waters. The American freshwater drum (*Aplodinotus grunniens*) is found all the way from Guatemala to Canada. It does not return to the sea. Of considerable interest was the finding some years ago that several species of sciaenids would survive in the salty inland Salton Sea of California. These fishes were introduced from the Gulf of California.

The Atlantic croaker (*Micropogon undulatus*) normally ranges in size from 1 to 4 pounds (0.5 to 1.8 kilograms). It is found from Argentina northward to Massachusetts. The channel bass or redfish (*Sciaenops ocellata*) is not a bass, but is associated with the croaker family. This is quite a large fish, attaining a length of over 50 inches (1.2 meters) and a weight of over 80 pounds (36 kilograms). It is found in the Gulf of Mexico and from Florida northward to Massachusetts. The California white sea bass of the genus *Cynoscion* (*C. nobilis*) and the Atlantic weakfish or common sea trout are also so associated. Occurring in the Gulf of California and weighing up to 225 pounds (102 kilograms), the totuava (*C. macdonaldi*) is the largest member of the family. The spot (*Leiostomus xanthurus*) is found from Texas in the Gulf all the way around to Cape Cod.

Croakers of the genus Nibea are well known for their assemblage in schools of millions of fish and for the synchrony of their drumming noises. They are found in Japanese waters. A very few croakers make no noise because they do not have air bladders. These include a number of Atlantic species-the king whiting (*Menticirrhus saxatilis*), the gulf minkfish (*M. focaliger*), as well as the California corbina (*M. undulatus*).

CROCIDOLITE (Blue Asbestos). The mineral crocidolite may be considered as a fibrous variety of the monoclinic amphibole, riebeckite. It is also known as a massive mineral. Its hardness is 4; specific gravity, 3.2–3.3; luster, silky to dull; color, blue or bluish-green. It is found in Austria, France, Bolivia, the Republic of South Africa (the variety known as tiger's-eye); and in the United States, in Massachusetts and Rhode Island. The name crocidolite is derived from the Greek, meaning to weave, in reference to its fibrous appearance. See also **Cat's-Eye**.

CROCODILES AND ALLIGATORS. Of the class *Reptilia* (reptiles), subclass *Anapsida*, order *Crocodylia* (crocodiles), and suborder *Eusuchia*. Crocodiles are of the family *Crocodilidae*; alligators of the family *Alligatoridae*. The gavials (*Gavialidae*) are closely associated with crocodiles and alligators.

The *Crocodylia*, a uniform group of unmistakable animals, includes the largest modern reptiles. Some of them are said to live for a century, although such an advanced age has not been proved. An American alligator is reported to have lived for 56 years in a zoo; a Nile crocodile has been reported living up to 45 years in captivity. Since crocodilians become much larger in the wild than when confined, it is possible that free-living animals can reach a correspondingly greater age. Crocodilians are characterized by a lizard-like shape and an armored skin, which covers the whole body with large, strong, and partially ossified horny plates.

Apart from one species found only in brackish and sea water, crocodilians live near fresh water shores in the warmer regions of the earth. Although they move about most efficiently in the water, they use various gaits on land-sliding slowly on the belly, stepping along with the legs extended so that the belly does not touch the ground, and even galloping for short distances by moving the fore and hind legs, much as a jackrabbit does when it hops. The forelegs end in five fingers, separated down to the base, while the four toes which terminate the hind legs are more or less completely connected by webbing, with the three inner toes bearing strong claws. Despite the fact that they are webbed, the feet are not the basis of locomotion in water; rather, the animals swim entirely by serpentine movements of the body or mighty strokes of the laterally flattened, oar-like tail. There is a characteristic comb or crest of tall scales on the tail, double near the base and single from the middle of the tail to its tip. Crocodilians can float in water with the body and tail angled downward, leaving only the nostrils, eyes, and ears above the surface; they evidently do this by suitably distributing the air in the lungs.

Crocodilians are of large to very large size, with lengths up to 7 meters (over 20 feet) or more. In some species, the males grow larger than the females. The skin on the head is firmly fused to the skull; on the neck there are groups of large, sharply ridged bosses, whose number and arrangement can be used in the identification of certain species. The back is covered by thick, rectangular, horny plates, partially ossified on the underside. The plates on the ventral surface are smaller, and only among the alligators and in a few crocodiles are they completely ossified. Where dermal ossifications do exist, they are flexibly connected to one another. There are ribs on all the trunk vertebrae, the sacral vertebrae, the first 5 to 10 tail vertebrae, and, in addition and in contrast with all other modern reptiles, even on the two cervical vertebrae. In the abdominal region, there are not only 8 pairs of true ribs, but also 7 or 8 pairs of abdominal ribs or gastralia, lying free in the musculature.

The teeth are situated in deep hollows (alveoli) in the jaws, and usually are rather variable in form and size. The teeth serve only for seizing and holding the prey, not for chewing. Since the thick tongue is firmly fused to the floor of the mouth, it can barely be moved. A long esophagus leads to the rounded, muscular stomach, which in contrast with most other reptiles is distinctly divided into an anterior and a posterior section. Young crocodilians feed mainly on insects, worms, and the smallest fish. As they grow larger, they tend to prefer fish and turtles. Older crocodilians also eat birds and small mammals and frequently larger decayed mammals. Feeding occurs only in the water, but not underwater. After rapid, thorough digestion, the remnants appear as uniformly shaped droppings. The indigestible parts of the prey, such as feathers, are spit out in a mass.

The nostrils lie on the raised tip of the nose; they can be closed by folds of skin. A long nasal passage leads from the nostrils to the choanae, which open far back on the palate. These also can be closed off by a flap of skin in the mouth. Because of this arrangement, crocodilians can lurk under water with their mouths open and still breathe, as long as the nostrils are above the water surface. Since the heart is almost completely divided into four chambers, oxygenated blood and oxygen-poor blood do not mix within it; they do mingle, however, at a perforation near the base of the aortic arches. The arrangement is such that the pulmonary artery receives deoxygenated blood; the right systemic arch (which supplies the head) receives oxygenated blood; the left systemic arch receives mixed blood. This pattern of circulation may well be related to their ability to remain submerged for long periods. Small crocodilians have been known to stay underwater for 45 minutes and the larger ones for over an hour, without breathing.

The eyes have both an upper and lower lid, as well as a semitransparent nictitating membrane, which can be drawn over the front of the eye from the inner corner. In contrast with all other reptiles, crocodilians have an external ear-a fold of skin that can be closed over the eardrum.

All crocodilians reproduce by means of white, hard-shelled eggs of about the same size as chicken or goose eggs. The eggs are porous on the surface and weigh between 40 and 90 grams. The females care for the young, occasionally in quite an elaborate manner. When the young are ready to hatch, they break the egg with the egg caruncle, a horny protuberance on the tip of the snout. At first, their voices are squeaky, but as the animals grow there is a transition to a dull roar.

Most scientists divide present-day crocodilians into three families: (1) alligators (*Alligatoridae*), in which the fourth tooth of the lower jaw fits into a laterally closed pit in the upper jaw, while the fourth tooth of the upper jaw is best developed. See Fig. 1. (2) Crocodiles (*Crocodylidae*), in which the fourth tooth of the lower jaw is laid into a notch in the upper jaw, open at the side, so that it is visible when the mouth is closed, while the largest tooth of the upper jaw is the fifth. See Fig. 2. (3) Gavials (*Gavialidae*), a single species in which the snout is greatly lengthened and the teeth are all of the same size and shape.

Alligators. The alligators are New World animals, with the exception of the *Chinese alligator* (*Alligator sinensis*), which achieves a length of about 2 meters (6.4 feet) and occurs in the lower reaches of the Yangtze River. The best known species is the *American alligator* (*A. mississippiensis*), which attains a length of up to 6 meters (nearly 20 feet). This species occurs in the southeastern United States. The fingers of the American alligator, as well as the toes, are joined at the base by webbing. For many years, these animals were intensively hunted for their skins, which found many useful purposes. Regulations have been put in place to protect the alligator. Because of past hunting, it became difficult to find a specimen over 3 meters (9.8 feet) long.

Caimans of the alligatorid genus *Caiman* are found from Central America to the central part of South America. They live in the backwaters

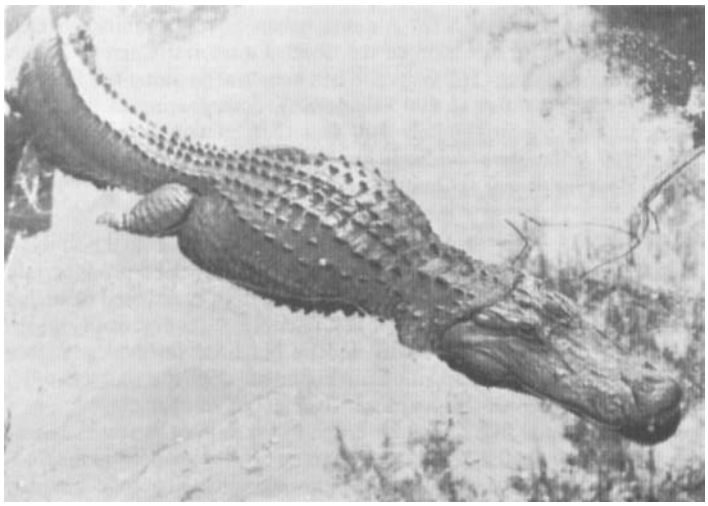

Fig. 1. Alligator. (*A.M. Winchester*.)

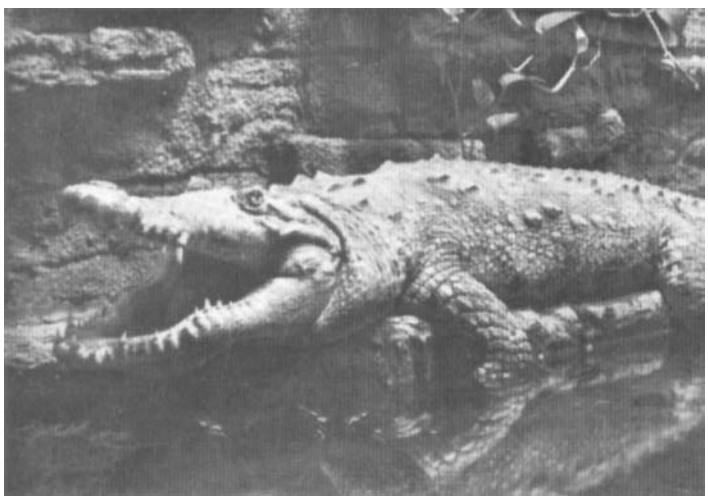

Fig. 2. Crocodile. (*A.M. Winchester*.)

of rivers or in very slowly flowing waters with muddy bottoms and soft sand banks. There is a ridge on the head running between the eyes like the bridge of a pair of glasses. The bony plates (osteoderms) of the belly armor are particularly well developed. The caimans are dark olive in color. There are two principal species-the *spectacled caiman* (*C. crocodilus*), which achieves a length of about 2.5 meters (8.2 feet) and the *broadnosed caiman* (*C. latirostris*), which is just slightly smaller than the spectacled caiman. A third species is the *black caiman* (*Melanosuchus niger*). The basic color of the black caiman is black, but young animals have yellowish spots and stripes. This species lives in central South America. Since this species, the largest of the caimans, preys on quite large animals that are valued by human hunters, efforts are made to minimize the population of the black caiman. The black caiman attains a length up to 4.7 meters (15.4 feet).

Crocodiles. These animals are found in tropical regions all over the world. The iris is greenish or yellowish; on either side of the upper jaw there are no more than 19 teeth. The majority of crocodilians belong to the genus *Crocodylus*, with 11 species.

The *Orinoco crocodile* (*C. intermedius*) attains a length of some 7.2 meters (23.6 feet) and occurs in the regions of the Orinoco and Amazon rivers in South America. The *American crocodile* (*C. acutus*) is about the same length. The range is large, extending from southern Florida across Central America into northwestern South America and the Antilles. *Morelet's crocodile* (*C. moreleti*) is considerably smaller, attaining a length of about 2.5 meters (8.2 feet). This species occurs in Mexico, Honduras, and Guatemala and is similar to the American crocodile, but is distinguished by a rounded protuberance in front of the eyes. Additionally, there are the *Australian crocodile* (*C. johnsoni*) with a length of about 3 meters (9.8 feet), and the *New Guinean crocodile* (*C. novaeguineae*) with a comparable length and which lives in New Guinea, the Sulu Archipelago, and other Philippine Islands. This species is noted for its long snout. The *salt-water crocodile* (*C. porosus*) attains a length over 7 meters (22.9 feet) and, like the American crocodile, can swim into the open ocean and thus has extended its range over a very large area. It is found from southern India across the Sunda Islands, the Philippines, the Moluccas, New Guinea, the Solomons, and the New Hebrides, as far as northern Australia. The salt-water crocodile lives primarily in coastal areas, both in the sea and in brackish water. Occasionally, animals driven out to sea by the wind make astonishingly long voyages. It has been reported that a salt-water crocodile arrived at the Cocos Islands in the Indian Ocean, after having traveled at least 1100 kilometers (684 miles). This species, like other species of crocodile that consume foods with a high-salt concentration, must be able to dispose of excess salt. This is done by way of the lacrimal glands and the glands associated with the nictitating membranes, which in these crocodiles correspond in both structure and function to the salt glands of sea birds. An identifying characteristic of the salt-water crocodile is the double row of bosses forming ridges on the upper surface of the snout.

Nile Crocodile. This animal (*C. niloticus*) attains a length up to 7 meters (about 23 feet) and once inhabited all of Africa. Since it, like the salt-water crocodile, does not hesitate to go out to sea, it was able to colonize various islands off the coast, and its range includes Madagascar. In the early 1900s, the Nile crocodile was exterminated in what was then called Palestine, and it is now no longer to be found below the second cataract of the Nile, i.e., in Egypt.

Only in a few parts of Africa-for example, at Murchison Falls in Uganda-can one now be certain of an opportunity to observe many large Nile crocodiles at relatively close range. They were so numerous earlier in this century in various parts of Africa, such as Tanzania, that bounties were offered for killing them. Humans have hunted crocodiles because the crocodiles attack domestic animals and occasionally humans, but for a long time this activity had little effect upon the crocodile population. In later years, the value of the skins greatly increased hunting. In recent years, regulations have been installed by some countries in an effort to protect this species.

Crocodilians are important elements of the biota where they live. Usually the large crocodilians spend the night in the water and lie in the sun on land for most of the day; only at midday do they withdraw to the shade or cool themselves briefly in the water. With the onset of darkness, they leave the shore again. Although they are poikilothermic (cold-blooded) animals, they manage in this way to keep the body temperature relative constant-at an average value of 25.6 °C, with brief excursions of a few degrees up or down. On land, in the midday heat, crocodilians tend to lie with the mouth wide open. In the absence of sweat glands on the body, this method permits water evaporation from the mucous membranes of the mouth-something like the panting of a dog. Crocodilians are seldom if ever encountered in open water of lakes.

The mouth-opening behavior of crocodiles was mentioned by the Greek historian Herodotus (490–424 B.C.), who reported that a bird, the trochilus, slips between the jaws and picks off leeches there. This has not been proved, but there is an association between certain birds and the crocodiles. The common sandpiper (*Tringa hypoleucos*), which breeds in Europe and spends the winter among the crocodiles, picks off the parasites from their bodies and even runs to meet the crocodiles when they come out of the water. Most modern zoologists do not believe that birds actually go into the open mouths and clean the teeth.

Fully grown crocodiles in South Africa's Kruger National Park kill primarily antelopes, such as the impala, bushbuck, and waterbuck, but they also attack other animals, such as giraffes, buffalo, and young hippopotamuses, wild dogs, porcupines, and lions. Their main food in Kruger Park consists of turtles. It should be mentioned that crocodiles have killed more humans than all of the predatory mammals and poisonous snakes found in Kruger Park. Often crocodiles will consume the remains of dead animals. The teeth of the crocodiles are not suited for tearing apart or chewing up large prey. In the case of a hippo or buffalo that has recently died, the crocodiles can at first only bite off the ears and the tail, for the skin is too firm. For this reason, they often push dead animals into underwater hollows along the banks, so that the skin softens and decay begins.

Several species of crocodile make provisions for their young. Incubation of eggs is not uncommon.

Initially, crocodiles grow rapidly. In the first 7 years, the Nile crocodile increases in length by an average of 26.5 centimeters (10.4 inches) per year. Growth slows as the animal ages. The male animals become sexually mature when at a length of 2.9 to 3.3 meters (9.5 to 10.8 feet). Females do not lay eggs until they are 8 to 12 years old.

Gavialidae. Only one genus of this family of crocodilians remains, the *Indian gavial* (*Gavialis gangeticus*), which attains a length of about 7 meters (22.9 feet). The origin of this species is perhaps to be found among the long-snouted crocodiles of the Cretaceous. The snout is about 3.5 times as long as it is broad at the base.

The Indian gavial is the crocodilian most strictly limited to life in the water. Its legs are quite weak, whereas the oar-like tail is particularly powerful. The gavial lives in the deep, flowing waters in the regions of the Ganges, Mahanadi, and Brahmaputra Rivers of India, as well as in the Koladan River at the mouth of the Maingtha in southeastern Asia. The females, like all crocodilians, lay their eggs on the land, usually on sandbanks.

CROCOITE. The mineral crocoite, lead chromate, corresponds to the formula $PbCrO_4$, and forms prismatic monoclinic crystals, often acicular. It is also found in columnar or granular masses. It has a rather distinct cleavage parallel to the prism, and a less distinct cleavage parallel to the base. It has a conchoidal fracture, is sectile; hardness, 2.5–3; specific gravity, 5.9–6.1; luster, adamantine to vitreous; color, red; streak, orange-yellow, translucent. Crocoite is a secondary mineral believed to be formed by waters containing chromic acid acting upon lead minerals like galena, with which it is associated. It is found in the former U.S.S.R., Rumania, Tasmania, Brazil, the Philippines, and Arizona. It is not of commercial importance. The name crocoite is derived from the Greek word for saffron in reference to the color of the powdered mineral.

CROISSANTS AND DANISH. See **Bakerry Process, Yeast-Raised Products**

CROMWELL CURRENT. A dense ocean current running beneath and in the opposite direction of the South Equatorial Current. It was discovered at a point 150° West and has been traced along the Equator for nearly 3,500 miles (5,600 kilometers), disappearing at the Galapagos Islands. Approximately 700 feet (210 meters) thick and 250 miles (400 kilometers) wide, it has a velocity of approximately 3.5 miles (5.6 kilometers) per hour.

CROOKES TUBE. Sir William Crookes was a pioneer in the study of electric discharge in gases. In the vacuum tubes that he used, certain forms of which still bear his name, the pressure was reduced to such a point that the bright glow observed at higher pressures practically disappeared. The cathode rays, obstructed by but little residual gas, shot straight across the tube and, impinging upon the opposite wall, caused it to glow with greenish fluorescence. By placing an obstacle, such as a metal plate shaped like a Maltese cross, in the path of the rays, he was able to demonstrate their rectilinear character by the shadow on the fluorescing surface. In one type of tube he interposed a light paddle wheel of metallic vanes in the path of the rays, and found it driven at high speed as if by a stream of air. It is, however, probable that the greater part of this effect is due to the heating of the bombarded surfaces and that the paddle wheel really operates as a Crookes radiometer. See Fig. 1.

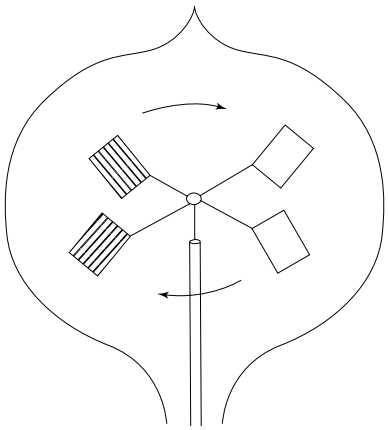

Fig. 1. Four-vane radiometer in bulb.

CROP. A thin-walled expanded portion of the alimentary tract (see also **Digestive System (Other Life Forms)**) used for the storage of food prior to digestion. Crops are found in many animals, including earthworms, insects, and birds.

CROP MOISTURE INDEX (CMI). The Crop Moisture Index (CMI) uses a meteorological approach to monitor week-to-week crop conditions. It was developed by Palmer (1968) to assess short-term crop water conditions and needs across major crop-producing regions. It is based on the concept of abnormal evapotranspiration deficit, calculated as the difference between computed actual evapotranspiration (ET) and computed potential evapotranspiration (i.e., expected or appropriate ET). Actual evapotranspiration is based on the temperature and precipitation that occurs during the week and computed soil moisture in both the topsoil and subsoil layers.

CROSSBEDDING. Oblique lamination of certain beds in aeolian or water-laid sediments, caused by current action, is called crossbedding. Crossbedded sediments are found especially in river and stream deltas, alluvial fans and cones, river sand bars and marine sand deposits, and are also characteristic of windblown deposits of all kinds. The different types of crossbedding are useful criteria for helping to determine the physical (including climatic) conditions under which certain types of clastic sediments were deposited. In regions where the formations have been highly deformed, and possibly overturned, crossbedding may also be used by the stratigrapher and structural geologist to determine the original order in which sedimentary strata were laid down.

CROSSCORRELATION DETECTION. A method of detection in which a signal is compared, point-to-point, with an internally generated reference. The output of such a detector is a measure of the degree of similarity of the input and reference signals. The reference signal is constructed in such a way that it is at all times a prediction or best estimate of what the input signal should be at that time.

CROSS LINKING. See **Rubber (Natural)**.

CROSS MODULATION. This is an effect produced in radio receivers which results in the modulation from one carrier being impressed on another carrier. If two modulated carriers are applied to the input of a transistor that has appreciable curvature in its operating characteristic, there will be numerous frequency components in the output of the tube. However, following selective or tuning circuits will discriminate against many of these but there will be certain ones which will not be eliminated. Some of these represent the sidebands of the modulation of the undesired signal modulated on the desired carrier. Since they occupy the same frequency band as the desired carrier and its normal modulation there is no way in which they may be filtered out, and hence upon detection the audio output will contain both the desired and the undesired audio signals.

CROSS SECTION. From its general meaning of a section at right angles to an axis, the term cross section has been extended to mean a measure of the probability of a particular process. It is expressed in units of area, although it is not usually identical with the geometric cross section across which the process occurs. For a collision reaction between nuclear or atomic particles or systems, the cross section is an area such that the number of reactions occurring is equal to the product of the number of target particles or systems multiplied by the number of incident particles that would pass through this area at normal incidence. If n_t is the number of target nuclei or other particles per unit volume (cm^{-3}) of a substance exposed to an incident beam consisting of n_0 particles per unit area and unit time (cm^{-2} sec^{-1}), then the interaction cross section $\sigma = N/n_0 n_t$, where N is the number of reactions of a specified type per unit volume and unit time (cm^{-3} sec^{-1}). The *macroscopic cross section* $\sum = \sigma n_t$ is the cross section per unit volume for the process under consideration. Nuclear cross sections include a cross section for fission, a cross section for capture, and a cross section for scattering both elastic and inelastic. Atomic cross sections include the cross section for Compton collision and the cross section for ionization by electron impact. The *total cross section* is the sum of the separate cross sections by which a particle can be removed from a beam. In nuclear processes the customary unit of cross section is the barn.

CROSS SECTION (Meteorological). In weather analysis and forecasting, a graphic representation of a vertical surface in the atmosphere, along a given horizontal line or path, and extending from the earth's surface to a given altitude.

The type of data and analysis presented on such a cross-sectional chart depends upon its purpose. In meteorology, a synoptic cross section is prepared from synoptic weather data. In aviation, a flight cross section (or route cross section) is a graphic forecast of conditions expected to be encountered along the proposed flight route; therefore, time varies along the horizontal axis of the chart.

CROSS-STAFF. In the period prior to the invention of the sextant in the eighteenth century, both the cross-staff and the astrolabe were used by navigators for the purpose of measuring altitude of celestial objects. The astrolabe was the more compact of the two, but the cross-staff was simpler to use, and the results were slightly more accurate, particularly for measuring small altitudes.

The principle and use of the instrument are illustrated in Fig. 1. A "cross," with a peep sight in its upper end, slides along a rod EB. Holding the cross in a vertical position, the observer sights from E along the rod toward the horizon at H, and slides the cross along until the object under observation appears through the peep sight in the cross. The graduations on the rod indicate directly the value of the angle HES, which is the desired apparent altitude. The instrument may also be used to measure the angular distance between any two objects.

Within recent years, the instrument has been used to some extent for teaching purposes in elementary courses in astronomy.

See also **Astrolabe**; **Navigation**; and **Sextant**.

CROSSTALK. This is the undesirable operating condition of a communication system where the electrical effects of one circuit produce an undesired current in another. In the case of a phantom telephone circuit, crosstalk will be troublesome unless the lines with loading coils, terminal equipment, etc., are perfectly balanced electrically. Considerable care must be taken in the manufacture of the loading units in order to minimize crosstalk. See also **Inductive Interference**.

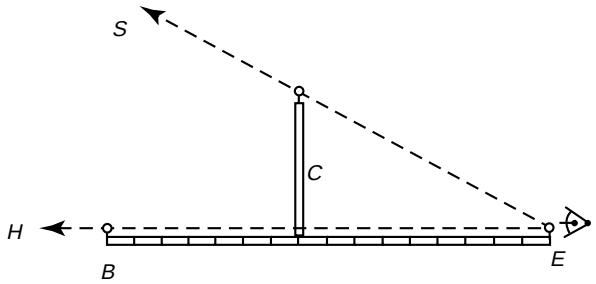

Fig. 1. Cross-staff shown schematically.

CROSS WIND. See **Winds and Air Movement**.

CROTON BUG *(Insecta, Orthoptera).* A European cockroach, one of the two chief pests of this kind in the United States. Its name is said to be due to its association with water pipes from the Croton reservoir, which serves New York City.

CROW *(Aves, Passeriformes).* Large birds of the Northern Hemisphere and Africa. They are black or black and white in color. Together with the ravens, rooks, magpies, jays, and other species they make up the crow family (*Corvidae*).

The importance of the common crow of North America, *Corvus brachyrhynchus*, has been debated. The bird does some good in destroying vermin and insects, but the farmer and conservationist are both against it for its destruction of fruit and grain and the eggs and young of other birds.

The crow is omnivorous and gregarious. It is remarkably intelligent as compared with most other birds. Its plumage is soft, dense, and dark. The common North American crow measures about 20 inches (51 centimeters) in length. The tail is composed of 12 feathers. The nest is usually located high in tree tops and is often repaired and used a second or third year. The egg is blue-green with dark markings and of obtuse shape. There are usually five eggs. The female incubates the eggs, but the male assists in feeding the young. The crow lives for many years. These birds prefer large communal rookeries, sometimes inhabited by several tens of thousands of birds. The birds may commute from 30 to 40 miles (48 to 64 kilometers) daily in each direction from the rookery to other points. It is difficult for naturalists to study crows because they are very difficult to approach, using an effective system of sentries to warn of approaching danger. The crow's thieving characteristics are well established.

The fish crow (*C. ossifragus*) is a somewhat smaller bird and is found along tidewater areas. Whereas the common crow eats a variety of foods, from carrion to insects, seeds, fruits, reptilian eggs, and even sometimes small reptiles, the fish crow has a diet of shellfish.

The jackdaw (*C. monedula*) is a small, gregarious European crow, typically with a gray collar, but also occurring in a wholly black form. These birds are common in Zurich. Both sexes build the nest. Another species of daw occurs in Asia and flocks are usually seen around the temples of the Chalimar Gardens of Kashmir. The term daw also is sometimes used to refer to a great-tailed grackle found in the southwestern United States.

CRUCIBLE. A crucible is a vessel made of heat-resistant material and employed to hold a material that is at high temperature, or is to be subjected to high temperature. Crucibles will range in size from the small laboratory types to large ones having a capacity of several tons of molten metal. They are roughly cup- or barrel-shaped, and are made of some material such as clay. In the laboratory, platinum, iron, and porcelain crucibles are used. In the iron and steel industry, clay crucibles have been used, but at the present time most manufacturers employ the graphite crucible, which is made half and half from graphite and fireclay, well-mixed, molded, and burned to vitrification. The crucible may be used to hold a material being melted or burned, as in some processes for making steel, where the raw material is put in the crucible, which is then set in a hot furnace until the contents are melted. Or, a crucible may be used to receive molten metal,

which has been produced elsewhere, as from a brass furnace or cupola, in which case it is the means for conveying it from the point of melting to the point of casting, serving thus as the intermediate reservoir between the furnace and the mold. See also **Casting**.

CRUNODE. A point on a curve through which there are two branches of the curve with distinct tangents.

See also **Tangent (Geometry)**.

CRUSTACEA. The lobsters, crabs, barnacles, shrimps, and many other species, constituting a class of the phylum *Arthropoda*. A large majority of the 25,000 known species are aquatic.

The Crustaceans are distinguished from other classes of the phylum by the following characteristics: (1) The body is divided into cephalothorax and abdomen. (2) The eyes are compound. (3) Two pairs of antennae are present. (4) Jointed appendages are found on the abdomen on many species. (5) Respiration is usually by gills.

The principal economic importance of crustaceans is due to the value of some species as food. Lobsters, shrimps, and some of the crabs are caught in large numbers for the market and are regarded as delicacies. Although formerly plentiful, the lobster has been caught in such large numbers on the New England coast of the United States that it now has to be protected by law and brings high prices. The smaller crustaceans are important as food for fishes.

Barnacles have long been a nuisance for their part in the fouling of ship bottoms.

The following indicates the complexity of classification of the crustaceans:

Subclass I. *Branchiopoda*. Varying number of body segments with appendages of uniform character, generally foliaceous; abdomen devoid of appendages; carapace usually present.
- Order *Anostraca*. Carapace not developed; eyes stalked. Fairy shrimp.
- Order *Notostraca*. Large dorsal shield-shaped carapace; eyes sessile. Apus.
- Order *Conchostraca*. Carapace divided into two valves enclosing entire animal. *Cyzicus*.
- Order *Cladocera*. Bivalved carapace enclosing trunk but not head. Water fleas.

Subclass II. *Ostracoda*. Bivalve carapace, not more than four pairs of appendages on the trunk. *Cypris*.

Subclass III. *Copepoda*. No carapace, usually five pairs of limbs. *Cyclops* and the parasitic fish-lice.

Subclass IV. *Branchiura*. Parasitic, compound eye and suctorial mouth. *Argulus*.

Subclass V. *Cirripedia*. Sessile as adults, usually six pairs of biramous cirriform appendages in body region; limbless rudimentary abdomen. Calcareous plates support carapace.
- Order *Thoracica*. Nonparasitic. *Lepas, Balanus*.
- Order *Acrothoracica*. Boring in shells of Molluscs, fewer than six pairs of trunk appendages. *Alcippe*.
- Order *Ascothoracica*. Parasitic, six pairs of trunk appendages; mouth appendages modified for piercing and sucking. *Petrarca*.
- Order *Apoda*. Parasitic, without mantle or trunk appendages. *Proteolepas*.
- Order *Rhizocephala*. Parasitic, body undergoes extreme degeneration. *Sacculina*.

Subclass VI. *Malacostraca*. Carapace normally present; many appendages on thorax and abdomen.
- Series I. *Leptostraca*. Abdomen with seven segments and telson. Thoracic appendages foliaceous, abdominal biramous. *Nebalia*.
- Series II. *Eumalacostraca*. Six abdominal segments and telson; thoracic appendages leg-like but seldom uniform.
  - Division 1. *Syncarida*. No carapace; first thoracic segment united with head or marked off by a groove.
    - Order *Anaspidacea*. Thoracic appendages with exopodites and lamellar epipodites (gills). *Anaspides*.
  - Division 2. *Peracarida*. Carapace when present leaves at least four of the thoracic segments free.
    - Order *Mysidacea*. Carapace extends over greater part of thorax but fuses dorsally with no more than three segments. *Mysis*.
    - Order *Cumacea*. Carapace coalesces with first three or four thoracic segments and encloses a branchial cavity on each side and forms a rostrum in front. *Diastylis*.
    - Order *Tanaidacea*. Carapace coalesces with first two segments and encloses a branchial cavity. *Apseudes*.
    - Order *Isopoda*. No carapace; oval and flattened; marine, freshwater and terrestrial forms. Pill bugs, woodlice, *Ligia* and others.
    - Order *Amphipoda*. Similar to preceding order but laterally compressed; second and third thoracic appendages nearly always prehensile organ. *Gammarus*.
  - Division 3. *Eucarida*. Carapace forms a cephalothorax.
    - Order *Euphausiacea*. Thoracic limbs do not form maxillipedes. *Euphausia*.
    - Order *Decapoda*. First three thoracic appendages modified as maxillipedes with branchiae usually in series. Prawns, shrimps, lobster, crayfish, hermit crab, crabs.
  - Division 4. *Hoplocarida*. Cephalothorax short, branchiae on abdominal segment.
    - Order *Stomatopoda. Squilla*.

CRUSTACEANS (Edible). The crustaceans have been known from early in the earth's history and are considered a highly successful group in their adaptation to changing environmental conditions over the centuries. With their approximately 35,000 species, the crustaceans contain four times as many species as are found among the birds. See also **Crustacea**. Only a relatively few of these species, however, are of importance as food substances-either as food for direct human consumption, or as food or bait for other sea animals, or for use as crop fertilizers. The crustaceans, making up the class *Crustacea* (phylum *Arthropoda*; subphylum *Diantennata*) originated in the sea, and the majority are still marine in character, although some have assumed freshwater and even terrestrial habitats. From a total worldwide marine catch standpoint, crustaceans make up only about 3% of the total, only about one-half of the quantity of mollusks harvested. Marine fishes comprise nearly 90% of the total catch.

The principal classes of crustaceans of interest as food are: shrimp (about 62% of the crustacean catch); crabs (28%); lobsters; and crawfish and crayfish. The various edible crustaceans are of the order *Decapoda* (10 legs).

Crabs

The principal crab fisheries of the world are found along the Asian and North American coasts of the central and northern Pacific Ocean; along the shores of North America of the Atlantic Ocean; along the coasts of northern Spain and western France (Bay of Biscay), in the Atlantic south of Ireland, and in the North Sea. Smaller concentrations are found off Chile in South America; and off Brazil in the southwestern Atlantic.

The crab industry of the Pacific coast of North America extends from California northward to Alaska and essentially involves two species: (1) the king crab (*Paralithodes camtschatica*), and (2) the Dungeness crab (*Cancer magister*). Two species of lesser importance are the rock crab (*Cancer* spp.) and the tanner crab (*Chinoecetes* spp.). In Hawaii, a small fishery exists for the Kona crab (*Ranina ranina*). The king crab is confined essentially to Alaskan waters. The Dungeness crab is much more widely distributed and is sometimes referred to as the market crab in California.

The Dungeness crab inhabits shallow waters inshore and estuaries as well as offshore waters on sandy or mud bottoms up to 50 fathoms in depth. The abundance of this species has fluctuated significantly in some areas during the past few decades. Some authorities believe that these deviations arise from natural causes rather than overfishing. Fishery regulations are imposed by various states and generally provide for retention of male crabs above a size at which they have spawned at least once, but size limit is not uniform, ranging from about 16 to 18 centimeters (6.26 to 7 inches) across the carapace. Regulations usually prohibit the retention of female, soft-shell, and undersized male crabs, and provide for escape ports in the pots to enable the smaller females and undersized males to escape. A closed season is applied in some areas to protect the crabs during the molt and soft-shell stages.

In crabs, the oxygen-carrying pigment in the hemolymph is a copper hemocyanin rather than an iron heme compound as in the blood of higher animals. The copper heme pigment is relatively colorless in the hemolymph, but tends to develop an objectionable bluish color after the

crab is processed. The bluish color may become especially noticeable in canned crab meat during storage. Because iron and copper tend to promote discoloration, crab meat should be handled and processed without exposure to metals or metal-containing compounds.

Dungeness crab meat is high in protein (18–20%), very low in fat (0.7–1.1%), and has about 90 calories of food energy per 100 grams. The natural sodium level is relatively high, ranging from 153 to 329 milligrams per 100 grams, as compared with an average level of 68 milligrams per 100 grams in marine fish.

King Crab. This species (*Paralithodes camtschatica*) is an 8-legged, spider-like arthropod covered with spiny projections. Two degenerate legs especially modified for breeding are tucked under the rear carapace margin, thus qualifying it as a decapod. An adult male king crab measures up to 24 centimeters (9.5 inches) across the carapace. Females are considerably smaller. The meat is white with reddish covering and firm in texture. The subtle flavor of king-crab meat makes it popular in salads or as an entree. Meat content represents about 30% of body weight, with most meat being in the legs and shoulders.

King crabs are found in ocean waters from southeastern Alaska to Siberia. Commercial concentrations of king crab have been located in nearly all areas of Alaska, with fisheries conducted inside the continental shelf from southeastern Alaska westward to the Aleutian Islands, in the Bering Sea, and Cook Inlet. Asian fisheries are centered mainly in the Okhotsk Sea and western Kamchatka. Individual migrations of king crab have been recorded at a maximum of about 161 kilometers (100 miles). The norm, however, is dictated according to the habits of the species, which find it moving into shallow areas to spawn in late March and April and returning to deep-water trenches during the summer and early fall. Winter migrations are shoreward or toward offshore shallows where molting and breeding take place in the spring, thus completing the cycle.

A larval king crab is nearly microscopic, physically resembling a shrimp, and free-swimming. Within twelve weeks, characterized by heavy mortalities, the larva metamorphoses into a bottom-dwelling miniature king crab less than 3 millimeters (about $\frac{1}{10}$-inch) long. Young crabs band together in pods, consisting of thousands of individuals, apparently for protection against enemies. Podding, as a function of survival, continues until about the third or fourth years, when the carapaces of both sexes are about 9 centimeters (3.5 inches) long. In the fifth years, the crabs attain sexual maturity. The species may live up to 14 years of age. At maturity, a male king crab may weigh as much as 11.3 kilograms (25 pounds), have an overall leg span of 1.8 meters (6 feet), and contain about 1.8 kilograms (4 pounds) of recoverable meat.

Red Crab. The deep sea red crab (*Geryon Quinquedens*) occurs along the edge of the continental shelf from Nova Scotia to Cuba and specimens are found in the Gulf of Mexico and off the coast of Brazil. The crab is generally found where the water temperature is between 3.3 and 5 °C (38–41 °F). South of New England, the crab is rarely found in waters less than 170 fathoms deep and the larger concentrations are usually at a depth between 250 and 300 fathoms. Further south along the coast, the crab will stay deeper and specimens in the Gulf of Mexico and off Brazil are caught at about 700 fathoms.

The red crab is about twice the size of the blue crab and grows to a size of 1 kilogram (about 2.25 pounds). Females are more slender and grow to about 0.8 kilogram (1.25 pounds). The body of the crab is squarish and the walking legs are long and slender. On each side of the front edge of the carapace are five short spines or teeth, to which the scientific name *quinquedens* refers. This is not a swimming crab. The color is red or deep orange. On the average, 24% of the meat is in the claws, 36% in the legs, and 40% in the body. The crab meat has the same color as lobster meat (white and pink), but it is difficult with handpicking to remove all of the shell. Red-crab meat lends itself to pasteurization. Taste panels often rate pasteurized red-crab meat over that of blue-crab meat.

Blue Crab. This species (*Callinectes sapidus*) has supported the oldest crab industry in the United States. Records indicate that blue crab was known in the Chesapeake Bay as early as the 1630s. Most current landings of blue crab are out of Florida, Maryland, North Carolina, and Virginia. Meat yield is about 12% of live weight. The meat is highly perishable because cooking cannot be relied upon to fully sterilize it, and the extensive use of hand picking and packing is a major source of contamination. The great concentration of the industry is found around the Chesapeake Bay.

Stone Crab. This species (*Menippe mercenaria*) is harvested on the Gulf coast, mostly in Florida, with a small product for local consumption in Texas. The crab cannot swim and it lives mostly on shallow flats in high-salinity areas near oyster reefs. It possesses great strength and can crack the shell of a large oyster. Nevertheless, it has a mild disposition and is often taken by hand.

Other minor crabs collected for food usage include the rock crab (*Cancer irroratus*), usually referred to as the sand crab in New England; the Jonah crab (*Cancer borealis*), mainly of regional interest; the tanner crab (*Chionoecetes tanneri*), which is found on the continental shelf of the north Pacific Ocean and valued by the Japanese and Russians; and the Kona crab (*Ranina ranina*), the most important species caught in Hawaiian waters.

Lobsters

The principal lobster fisheries of the world are found along the western shores of the Atlantic Ocean from Labrador south to Florida, and off Brazil (Cape de São Roque); in the Caribbean; off the southern tip of Africa (Cape of Good Hope); in the western Pacific off Japan; in the south Pacific Ocean, east of New Zealand; in the waters east of Tasmania; in the Indian Ocean west of Australia; with smaller lobster fisheries located in the North Sea, in the Atlantic west of Ireland, in the English Channel, in the Bay of Biscay, along the west coast of Africa southward from Cape Blanco, and in the eastern Pacific in waters west of Colombia and Mexico, including Baja California.

The greatest lobster harvest is of three species of true lobsters: (1) the American lobster (*Homarus americanus*), representing about 50% of the total catch; (2) the European lobster (*H. gammarus*), representing about 30%; and (3) the Norwegian lobster (*H. norvegicus*), also sometimes referred to as the Dublin Bay prawn or scampi. The Norwegian lobsters generally are not sold alive because they are not hardy. Much of the catch is sold as frozen tail meats.

Along the New England coast, 30 pounds (13.6 kilograms) of lobster usually comprises 20 to 30 lobsters. In contrast, lobsters taken in the offshore fishery on the edge of the continental shelf may weigh from 10 up to 30 pounds (4.5 to 13.6 kilograms). Large lobsters are not as desirable in the live market, but since the giants are filled with succulent meat, an increasing number are being harvested, particularly for processing.

Shrimp

The fisheries for shrimps and prawns may represent only about 1% of the total catch of seafood, but they represent at least 5–7% of the total value. More countries land shrimp than nearly any other kind of marine product and in at least 20 countries, shrimp fishing is a substantial industry. The leading shrimp harvesters are the United States, Mexico, Germany (West), India, Japan, and Pakistan. Other large harvesters include Thailand, Korea, China, Ecuador, Chile, Malaysia, the Netherlands, Norway, Spain, Australia, El Salvador, Greenland, Denmark, Venezuela, Italy, France, Sweden, Colombia, and the United Kingdom. About half the world's supplies of shrimp come from Asian countries. The importance of this has increased considerably in recent years, particularly the harvests from India and Pakistan.

There are over 2000 known species of shrimps (*Natantia*). They inhabit all possible environments between the deep sea and fresh water, but mostly are marine. The body is usually laterally compressed, and a tail fan is present on the relatively long abdomen. Despite this, shrimps spend most of their time on the bottom, walking around on their five pairs of walking legs, or using them to dig in the sediment. The long first antennae, which are held close together, form a tube through which fresh water is brought to the body for respiration. See Fig. 1. Some species have great tolerance for changing environmental conditions. For example, the common shrimp (*Crangon crangon*) does well in the Wattenzee (the Netherlands) in large numbers, despite the great variations in temperature and salinity found in this body of water. The common shrimp feeds at night on other small crustaceans, worms, and mollusks; during the day, it hides in the soft mud. Its life expectancy is 3 years. During this time, a single female can produce up to 20,000 offspring.

Mariculture of pond-reared shrimp has been studied. These investigations have included ways to improve and stabilize shrimp production through better pond construction, water management, nutrition, and disease control. Microbial activity is one of the main causes of quality deteoriation

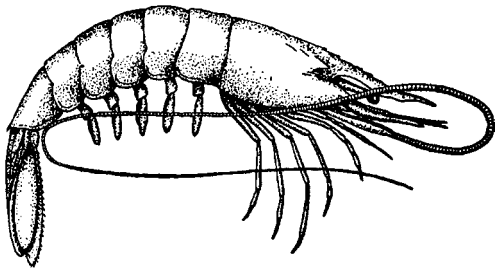

Fig. 1. Shrimp.

of harvested shrimp. It also can be a potential cause of foodborne diseases connected with shrimp.

Crawfish

Crawfish are sometimes referred to as "false lobsters" because of their similar appearance to lobsters.

Spiny Lobsters. This creature is actually a crawfish (suborder *Reptantia*, the crawlers) and can be distinguished from the shrimps (*Natantia*, the swimmers) by their dorsoventrally flattened bodies and usually powerfully developed pincers on the first pair of walking legs. The abdominal legs are no longer adapted for swimming, but are used by the female as the place to attach her eggs. The spiny lobster (family *Palinuridae*) is recognizable by its antennae, which are longer than the body, and the spiny processes of the carapace. Large, gripping pincers are lacking. Commercial use of spiny lobsters in all parts of the world is attributable to their meaty abdomens.

The European spiny lobster (*Palinurus vulgaris*) has a body length up to 45 centimeters (18 inches) and weighs up to 8 kilograms (17.5 pounds). These figures refer to mature specimens (10–15 years old). This species lives on the rocky coasts of the Atlantic and Mediterranean. It is a valuable food species. It feeds at night on snails, mollusks, and dead animals.

The Cape spiny lobster (*Jasus lalandei*) is a popular item on the menu in South Africa and Australia. The same is true of other *Palinurus* species on the coasts of North and South America. The American species (*Palinurus argus*) has seasonal migrations, during which the animals may walk for more than 100 kilometers (62 miles) along the bottom of the sea and thus be able to discover suitable areas with sufficient food. It is possible that the sounds the animal produces, discovered only relatively recently, aid in regulating these migrations.

One of the largest of the spiny lobsters is the New Zealand species (*Jasus verreauxi*), which can attain a weight of 13.6 kilograms (30 pounds) and a length of about 1 meter (3 feet). Most specimens, however, are considerably smaller.

Spiny lobster fisheries are based mainly in temperate and subtropic countries where the species of the genera Jasus and Panulirus are the basis for the fisheries.

Crayfish

The crayfish (*Astacidae*) are essentially restricted to the Northern Hemisphere. In the Southern Hemisphere, the ecological niche they occupy is taken over by the parasticids (*Parasticidae*) in South America and Madagascar (but not Africa), and in Australia by the austroastacids. The true crayfish is a freshwater crustacean. It reaches a length of about 15 centimeters (6 inches). See Fig. 2.

The European crayfish (*Astacus astacus*) lives only in clean water and hunts for food at night, feeding on both plant and animal material. Male crayfish can live up to 20 years. In recent years, partially because of pollution, crayfish populations have diminished. This has also been due partly to a fungus disease called "crab plague." The European crayfish population was seriously threatened in 1879 when it was nearly wiped out, and its return has been slow. The American crayfish (*Orconectes limosus*), introduced into Europe in 1890, is immune to the disease and also can survive in quite dirty water. Although it cannot be compared in size with European crayfish, it is now considered the most common inland crustacean used for human consumption.

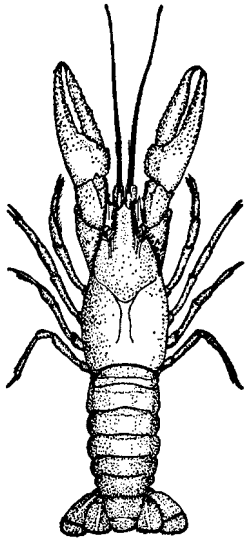

Fig. 2. Crayfish.

Antarctic Krill

Although the euphausids (*Euphausiacea*) seem almost shrimp-like, they can be distinguished immediately from the true shrimp, which belong to the *Decapoda*, by the end of the tail, which is covered with bristles. The lateral gills are not covered by the carapace, as in the case of the decapods. In addition, the maxillipeds, which are very well developed in the decapods, are lacking. The majority of euphausids are oceanic, inhabiting certain zones in enormous numbers, almost 100 million individuals per shoal. The inhabited areas are characterized by uniform temperatures and salinity, and each species of euphausid is so closely adapted to the environmental conditions in which it is found that it dies, or at least is unable to reproduce, if it drifts into a water zone with different conditions.

The enormous swarms of euphausids are an immense source of readily available food for many inhabitants of the oceanic regions, such as herrings, sardines, and other fishes. Even the giant blue whale and baleen whale sometimes feed exclusively on these tiny animals. The majority of euphausids feed by filtering plant and animal plankton; they make daily migrations up and down with their food source, their movements being dependent upon light intensity. At night, therefore, they are found near the surface and, during the day, at depths of several hundred meters. This can be demonstrated by echolocation, inasmuch as the euphausids form a scatter layer, which returns the echo.

The most important members of the euphausids belong to the "krill," as it is called by whalers. *Euphausia superba* inhabits cold seas; *Meganyctiphanes norvegica* lives on the edge of the Gulf Stream in Norway; in addition, members of the genus *Meatoscelis* and the carnivorous genus *Stylocheiron* should be mentioned.

The *Euphausia superba* achieves a length of 4 to 7 centimeters (1.5 to 2.75 inches). Krill is fundamental to the food chain of the Antarctic. Whales, seals, penguins, winged birds, various fishes, squid depend directly or indirectly on krill as a food source. Their existence has been known for many years, but no serious thought toward exploitation of krill commenced until the early 1960s. Krill harvesting and processing was pioneered by the former U.S.S.R., followed by the Japanese who produce krill meal and krill protein concentrate. It was in the early 1970s that the U.S.S.R. commenced to market krill butter and krill cheese products. The Japanese have made a type of fish sausage wherein 20% of the usual fish protein is replaced by krill. Products have also been introduced by Germany (West). Countries most active in krill research and harvesting have been the former U.S.S.R., Japan, Germany, Norway, Poland, Chile, and Taiwan. The Antarctic treaty signatory nations and the Food and Agriculture Organization (United Nations) have acknowledged the potential of krill protein and have recognized the need for proper management of the resource and harvesting limits.

Authorities have variously estimated the krill stocks from 125 to 200 million metric tons-to as high as 6 billion metric tons. These estimates admittedly have been based upon samplings conducted in relatively small areas. It has been estimated that baleen whales consume some 33 million

tons annually; crabeater seals another 100 million tons; fur seals, another 4 million tons; penguins, about 39 million tons. Some experts believe that marine fishes and squid consume another 100–200 million tons annually. These consumption figures, added together, exceed the smallest of the estimates of krill stock. On the other hand, this level of consumption represents less than 15% of the higher estimates. Thus, prior to aggressive exploitation of krill to meet some of the protein needs of humans, much more scientific information is required.

CRUX. Often referred to as the Southern Cross, this constellation consists of four bright stars, which form a figure of the approximate proportions of a Latin cross. The best known of the southern constellations, two of the stars are of the first magnitude and two are of the second magnitude. Located between Centaurus and Musca, the constellation lies above the Antarctic Circle and is not seen in northern latitudes.

CRYOCHEMISTRY. That branch of chemistry devoted to the study of reactions occurring at extremely low temperatures ($-200\,^{\circ}$C and lower). It permits synthesis of compounds that are too unstable or too reactive to exist at normal temperatures. See also **Cryogenics**.

CRYOGENIC HYGROMETER. A special type of chilled mirror hygrometer capable of measuring very low frost points.

These low temperatures at the mirror are attained by evaporating low boiling point or cryogenic fluids. This strong cooling capability allows cryogenic hygrometers to maintain reasonable response times even at low frost points. Cryogenic hygrometers are used for airborne humidity measurements from aircraft or balloons, but also in semiconductor industries for monitoring very dry environmental conditions needed in manufacturing processes.

CRYOGENIC MATERIALS. Those metals and alloys usable in structures operating at very low temperature, and usually possess improved strength properties at these temperatures.

CRYOGENIC PERIOD. An interval in geologic time during which geologic, geomorphic, and climatic conditions favored large-scale glacier formation; a period that tended to produce an ice age or glacial period. See also **Geological Time Scale**.

CRYOGENIC PROPELLANT. A rocket fuel, oxidizer, or propulsion fluid, which is liquid only at very low temperatures.

CRYOGENICS. The production and study of phenomena that occur at very low temperatures, i.e., below about 80K. The first step in attaining the required temperature generally involves the liquefaction of a gas or gases. Liquids can exist over a range of temperatures limited by the critical point at the higher end and the triple point at the low-temperature end. It is thus possible to compress a gas to the liquid phase at the critical point and to cool it by boiling under reduced pressure to its triple point. A series of gases having their critical and triple points overlapping can thus be used in a cascade process each being used as the refrigerant for the next in the series. Pictet used this method to liquefy oxygen, using methyl chloride and ethylene as refrigerants. There are, however, no liquids that cover the range from 77K to the critical point of hydrogen, or from 14K to the critical point of helium (5.2K). Thus, liquid hydrogen and helium cannot be produced by the cascade method.

Expansion of Gases. A gas may also be cooled by making it do work in the course of an expansion. When an ideal gas is expanded through an aperture into a constant volume, no work is done, since there are no interactions between the molecules and the molecules themselves occupy no volume. When a nonideal gas is so expanded, however, an amount of internal work. $(W = (PV)_{\text{final}} - (PV)_{\text{initial}})$ is done against the intermolecular forces. This work may be positive or negative, resulting in a cooling or heating of the gas. Air is cooled by this Joule-Thomson expansion at room temperature, but hydrogen and helium must be precooled to 90 and 15K, respectively to obtain further cooling upon expansion. Using this method, Kamerlingh Onnes first succeeded in liquefying helium in 1908. Compressed gases may also be made to do external work, for example, by expansion against a movable piston. In this case, the work is always positive and helium may be cooled and liquefied without any precooling by liquid hydrogen. See also **Ammonia**; and **Helium**.

With liquid helium readily available in the laboratory, research in the temperature range 5 to 0.8K has become commonplace. By using the isotope of helium ^{3}He, it is possible to attain temperatures down to about 0.3 K since the isotope has a lower boiling point than ^{4}He. This is about the lowest temperature practically attainable by boiling liquids at reduced pressure. To reach lower temperatures, it is necessary to use magnetic phenomena.

Magnetic Cooling. Although this concept dates back several decades, as of the early to mid 1993, this was one of the most seriously researched areas for designing supercoolers.

Debye and Giauque pointed out that at 1K the entropy of paramagnetic salts was still fairly large and, moreover, that it was almost all due to nonalignment of magnetic moments and that the entropy of lattice vibrations was very small. If the electron spins are aligned by application of a magnetic field, the entropy of the salt falls to a low value and the heat of magnetization can be extracted isothermally. The salt can then be thermally isolated and demagnetized adiabatically and its temperature will fall. Temperatures on the order of 0.01K can readily be reached by this method and the lower limit for a single demagnetization would appear to be about 10^{-3}K. When demagnetization occurs, the spin system reaches equilibrium temperature in about 10^{-10} seconds. It is found that equilibrium is achieved between the spin temperature and the lattice temperature by spin-orbit coupling in times on the order of a few seconds. Paramagnetic salts have relatively high specific heats at low temperature and hence the cold salt can be used to cool other bodies. However, making good thermal contact with the cooled salt can be difficult.

Kurti, Simon, and Gorter suggested that a further reduction in temperature could be attained if adiabatic demagnetization was performed on nuclear moments rather than the electron spin. The temperature which can be reached in an adiabatic demagnetization is determined by the point at which the entropy of the system in zero external field decreases sharply with decrease in temperature due to the alignment of magnetic moments, i.e., the point at which the interaction energy μh equals kT (h = internal field; μ = magnetic moment). Since the interaction energies of nuclear moments are much smaller than electron spin interactions, much lower temperatures should result. The materials used experimentally were metals cooled to 10^{-2} K by contact with a paramagnetic salt. The thermal isolation of the nuclear spins during demagnetization was achieved naturally by the nuclear-spin-conduction electron relaxation time ($\sim$100 seconds). Thus, while the nuclear spins cooled to between 10^{-5} and 10^{-6} K, the conduction electrons and lattice remained in thermal contact with the cooling salt at 10^{-2} K.

Magnetic Refrigerators. Magnetic cryogenic refrigerators are presently considered indispensable to the operation of future space-based defense

systems, increasing their efficiency, reliability, and life span. These coolers are designed to cool space-based infrared sensors and signal processors to temperatures lower than now practicable with conventional closed, gas-cycle coolers. Magnetic refrigerators employ what is known as the *magneto-caloric* effect, which cools by alternately magnetizing and demagnetizing a solid material. For example, a magnetic solid, such as gadolinium gallium garnet, can be continuously rotated through a strong magnetic field to produce temperatures even lower than gas-cycle coolers. Other possible applications for this new technology include space astronomical observators, space power generation, high-speed rail transportation, medicine, and the commercial gas liquefaction industry.

Another method of attaining temperatures below 1 K is to take advantage of the fact that the entropy of a superconducting metal is less than that of the metal in its normal state. Quenching of a superconductor by the application of a magnetic field can cause a cooling to about 0.1 K. However, since the specific heat of metals is very small at these temperatures, they are not very suitable for cooling other bodies.

Low-Temperature Measurements. Such measurements are usually carried out using secondary thermometers calibrated at certain fixed points previously determined on the absolute scale by a standard instrument. This instrument is generally a constant-volume gas thermometer used at low pressures. When the readings of this instrument are extrapolated to zero pressure, the scale coincides with the thermodynamic scale. In the range of 0.8 to 5.2 K, the vapor pressure of ^{4}He provides the most commonly used secondary scale and it agrees with the absolute scale to within 2 millidegrees over this range. The use of ^{3}He instead of ^{4}He increases the coverage to 0.3 K.

Resistance thermometers are useful over a wide range. For example, platinum is used from 273 to 15 K, and carbon covers the range 20 to 2 K and has the advantage of being quite insensitive to magnetic fields. The foregoing are examples of secondary standards where the scales are interpolated between fixed points.

For temperatures below 0.3 K, the susceptibility of a paramagnetic salt can be measured and the temperature calculated by extrapolation from Curie's Law $\chi = C/T$. This method gives true values for the temperatures so long as Curie's Law holds. Beyond this region, it is necessary to perform a thermodynamic cycle to determine the relationship between the magnetic temperature T^* and the absolute temperature T. The method of Kurti and Simon is to demagnetize adiabatically from a known temperature on the absolute scale, using a number of different field intensities, and hence to determine the relationship between T^* and the entropy S over the required range of temperature. Measurement of the amount of heat Q necessary to raise the temperature from T_1^* to T_2^* gives the absolute value of the average temperature $T_{1,2}$ from the relationship $\Delta Q = T\,\Delta S$. The heat is generally supplied to the salt by gamma rays, thus ensuring even heating of the sample, a necessary precaution since the thermal conductivity is poor. The problem of nonlinearity does not arise in the case of nuclear spin demagnetization since, in this case, the susceptibility obeys Curie's Law down to 10^{-7} K.

Cryogenic Phenomena

One of the most interesting phenomena of cryogenics is that of superconductivity, which was also discovered by Onnes. When metals are cooled from room temperature, their resistances decrease and at low temperature, they attain low values, which are fairly independent of temperature. Some metals, however, have a critical temperature below which their resistance goes to zero. Such a metal is known as a superconductor. See also **Superconductors**.

Superfluidity. As liquid helium is cooled below 2.18 K, it undergoes a sudden discontinuity of specific heat and a second-order transition to the superfluid state. In this state, the viscosity of the helium becomes a function of the method used to measure it. Measured by an oscillating disk method, the viscosity falls from 23×10^{-6} poise just above the transition to 1×10^{-6} poise at 1.3 K. Measured by passage through very fine capillaries, the viscosity is very nearly zero in the superfluid state. Hence, it is postulated that there are two coexisting, noninteracting fluids, one having the properties of non-"superfluid" helium; and the other having virtually zero viscosity and zero entropy. It is interesting to note that the thermal conductivity of superfluid helium is about 2,000 times greater than that of copper. This is the result of the motion of the entropy-free superfluid rather than normal thermal conductivity. See also **Superfluidity**.

Magnetic Properties. There are several fundamental experiments on the magnetic properties of materials that become possible as a result of the low-temperature environment of cryogenics. The first of these was discovered by deHaas and Van Alphen in 1930. They found that at low temperatures, the susceptibility of bismuth single crystals rose and fell periodically as the magnetic field was increased. Later work shows that the periodicity occurs in all metals at low temperatures and is the result of quantization of electron motion perpendicularly to the applied field. This effect was used to determine the Fermi surface of metals.

Radioactive Decay. The method of alignment of nuclear moments has been used to study radioactive decay as a function of nuclear orientation. The aligning field in this case can be either an externally applied magnetic field or an internal crystal field. One of the more striking of these experiments has been the test of the Lee-Yang theory of nonconservation of parity in weak interactions. A third fundamental experiment of interest was the confirmation of London's concept that flux through a superconducting ring is quantized. The ring was a lead tube of 10^{-3} centimeter diameter and it was suspended from a torsion balance. The tube was made superconducting in the presence of longitudinal magnetic fields, and the frozen-in flux was measured and found to be quantized.

Several practical applications of cryogenics technology are described elsewhere in this encyclopedia. Check Alphabetical Index.

An urgent need during the past decade concerns the transportation and storage of living organs for transplantation. Cryosurgery is described in the article on **Vision and the Eye**. Obtaining extremely low temperatures for superconductor research has been important during the past decade. See also **Superconductors**.

CRYOHYDRATE. An eutectic system consisting of a salt and water, having a concentration at which complete fusion or solidification occurs at a definite temperature (eutectic temperature) as if only one substance were present.

CRYOHYDRIC POINT. The eutectic point in cases in which the system contains water.

CRYOLITE. Cryolite, sodium aluminum fluoride, Na_3AlF_6, crystallizes in the monoclinic system but in forms that closely approach cubes and isometric octahedrons. It is usually found massive. Cryolite has an uneven fracture, is brittle; hardness, 2.5; specific gravity, 2.97; luster, vitreous to greasy; color, snow-white but may be colorless, reddish or brownish; translucent to transparent. The only considerable occurrence of cryolite is at Ivigtut, Greenland, where veins of this mineral are associated with granites and gneisses. Small occurrences of cryolite have been noted in the Ilmen Mountains. Russia, and at Pikes Peak, Colorado. Cryolite has its chief use in the electrolytic production of aluminum, but small amounts are employed in the manufacture of opalescent glass.

The name cryolite is derived from the Greek words meaning frost (ice) and stone in reference to its translucency.

The aluminum industry no longer uses the natural mineral for operation of electrolytic cells except infrequently for start-up operations. The synthetic cryolite used is produced by two main processes: (1) the sodium aluminate from the Bayer process (see also **Bauxite**) is reacted with hydrofluoric acid: $NaAlO_2 + 2NaOH + 6HF \rightarrow 3NaF \cdot AlF_3 + 4H_2O$; or (2) sodium carbonate may be used instead of NaOH:

$$NaAlO_2 + Na_2CO_3 + 6\ HF \longrightarrow 3\ NaF \cdot AlF_3 + CO_2 + 3\ H_2O$$

The quality hydrofluoric acid required for these reactions may be prepared from fluorspar: $CaF_2 + H_2SO_4 \rightarrow 2HF + CaSO_4$. Normally, cryolite is not considered toxic. A continued exposure to finely divided cryolite in the air may lead to *fluorosis*. However, the compound is toxic to insects.

S.J. SANSONETTI

CRYOLOGY. That branch of hydrology concerned with snow and ice.

CRYOMETER. A low-temperature thermometer.

CRYOPUMP. 1. An exposed surface refrigerated to cryogenic temperature for the purpose of pumping gases in a vacuum chamber by condensing the gas and maintaining the condensate at a temperature such that the equilibrium vapor pressure is equal to or less than the desired ultimate pressure in the chamber.

2. The act of removing gases from an enclosure by condensing the gases on surfaces at cryogenic temperature. Also referred to as a *cryogenic pump* and not to be confused with *cryogenic fluid pump* for *circulating cryogenic propellants*.

CRYOSCOPE. An instrument for measuring the freezing or solidification point. The Hortvet cryoscope is used for the estimation of added water in milk from the lowering of the freezing point.

CRYOSCOPIC CONSTANT. A quantity calculated to represent the molal depression of the freezing point of a solution, by the relationship

$$K = \frac{RT_0^2}{1000 l_f}$$

in which K is the cryoscopic constant, R is the gas constant, T_0 is the freezing point of the pure solvent, and l_f is the latent heat of fusion per gram. The product of the cryoscopic constant and the molality of the solution gives the actual depression of the freezing point for the range of values for which this relationship applies. Unfortunately, this range is limited to very dilute solutions, usually up to molalities of $\frac{1}{100}$, and must be modified for many solutes. See also **Freezing-Point Depression**.

CRYOSPHERE. One of the interrelated components of the Earth's system, the cryosphere is frozen water in the form of snow, permanently frozen ground (permafrost), floating ice, and glaciers. Fluctuations in the volume of the cryosphere cause changes in ocean sea-level, which directly impact the atmosphere and biosphere.

See also **Earth**; and **Ocean**.

CRYOTRON. A device based upon the principle that superconductivity established at temperatures near absolute zero is destroyed by the application of a magnetic field.

CRYPTATE COMPLEXES. See **Chemical Elements**.

CRYPTOCLIMATE. (or Kryptoclimate.) The climate of a confined space, such as the inside of a house, barn, greenhouse, or a natural or artificial cave.

This term is often replaced by the term microclimate, appropriately modified, for example, house microclimate. See also **Microclimate**.

CRYPTOCOCCOSIS. A systemic infection by Cryptococcus neoformans, a yeast that forms neither mycelia nor spores and reproduces solely by budding. The cells are spherical (5–15 μm in diameter); they are Gram-positive and have a large capsule containing a polysaccharide which is responsible for the slimy appearance of the yeast. The organisms can be isolated from the soil, fruit, and the skin and intestinal tract of normal humans. The most constant source of virulent strains is, however, soil enhanced in creatinine by pigeon droppings. The birds are not infected, although their crops may be heavily colonized. Very large quantities of the organism (1×10^7 yeasts/gram) may be found in droppings in highly populated urban areas. *C. neoformans* seems to meet with little resistance in the body and does not evoke the active inflammatory response seen in other fungus and bacterial infections.

Cryptococcus has been recorded from most countries of the world, although it is most prevalent in the United States and Australia. The portal of entry is usually the lung, followed by dissemination to other sites.

Pulmonary cryptococcosis is well recognized in the United States and presents as a chest infection with fever and cough associated with scattered areas of pulmonary infiltration as visualized in x-rays. In some patients no treatment is required and the whole process resolves itself quite rapidly. It is probably advisable, however, to give chemotherapy to those with the prolonged disease or underlying abnormalities.

Disseminated cryptococcosis must be distinguished from other diseases which present aseptic meningitis. Pyrexia, headache, and mental changes occur. Cryptococci can sometimes be found in the blood and urine and the cerebrospinal fluid, where also glucose content is seen to fall and protein to rise.

The prognosis of untreated meningitis is poor, with death ultimately occurring. Current treatment is a combination of oral fluorocytosine and intravenous amphotericidin. Cryptococci may be disseminated to other sites including liver and spleen, kidney, skin, or bones, and these manifestations should be kept in mind.

As reflected by the references listed, the incidence of *Cryptococcus neoformans* infections has had a rapid rise since the commencement of the acquired immunodeficiency syndrome (AIDS) epidemic.

CRYPTOCRYSTALLINE. When the texture of a rock is so finely crystalline (that is, made up of such minute crystals) that its crystalline nature is but vaguely revealed even in a thin section by transmitted polarized light, the rock is said to be cryptocrystalline. Among the sedimentary rocks, chert and flint are cryptocrystalline. Lava flows, especially of the acidic type such as felsites and rhyolites, may have a cryptocrystalline ground mass as distinguished from pure obsidian (acidic), or tachylite (basic), which are natural rock glasses.

CRYPTOCRYSTALLINITY. See **Mineralogy**.

CRYPTOGRAPHY. See **Encryption**; and **Internet Security**.

CRYSTAL. A macroscopic sample of a solid substance exhibiting some degree of geometrical regularity, or symmetry, or capable of showing these properties after suitable treatment (e.g., cleavage, etching, etc.). Almost all pure elements and compounds are capable of forming crystals.

A perfect crystal is one in which the crystal structure would be that of an ideal space lattice. No such crystals exist, all real crystals containing imperfections which have a strong influence on the physical properties of the crystal.

The mechanical and electronic properties of polycrystalline materials depend dramatically upon the boundaries between neighboring regions of different crystallographic orientation-that is the grain boundaries-and it is to these regions that minor alloying and impurity elements segregate. Their presence may be ascertained by high resolution transmission electron microscopy (HRTEM) and computer simulation.

Structure of Crystals. Early investigators suggested that the regular structure of crystals, embodied in the laws of crystallography, could be explained if they were thought of as built up by the repetition of equal polyhedral cells, fitting together to fill space, each cell representing a characteristic group of particles, perhaps the atoms and molecules of the compound. A rough calculation showed that the spacing of these units in many ionic crystals might be of the same order of magnitude as the wavelengths of x-rays, as deduced from quantum theory. Von Laue suggested, and verified, that diffraction of the x-rays occurs when they are passed through a suitably oriented crystal. He knew, from the density and atomic weights, that the number of atoms in a cubic centimeter of rock salt, for example, is about 4.488×10^{22}, and that therefore, if they are equally spaced in all three directions, their distance apart is 2.814×10^{-8} centimeters or 2.814 Å. Certain quantum theory calculations had already indicated that x-rays have wavelengths of this order. It occurred to von Laue that if a beam of x-rays were directed upon a crystal and the crystal turned into a suitable position, one might observe interference maxima analogous to those produced with light by a diffraction grating. This proved to be the case, and the result verified beyond question the existence of regular spacings between reflecting planes of some sort, presumably plane arrays of atoms or ions. The kind of pattern obtainable is demonstrated by Fig. 1.

Subsequent analysis of the problem by Bragg resulted in a formula analogous to that for interference of light reflected by thin plates. If the reflecting layers are spaced at equal distances d, and if the wavelength of the incident x-rays is λ, the angle θ between rays and layers necessary for an interference reflection maximum is given by Bragg's law, viz., $\sin\theta = n\lambda/2d$; in which n is an integer. By slowly turning the crystal, the various plane-families are brought into suitable orientations for the production of maxima. The result is a Laue pattern of black spots on the photographic plate placed beyond the crystal to catch the reflections. Another method, developed by Hull and by Debye and Scherrer, secures the necessary angular variation by crushing the crystal to powder and relying upon the fortuitous orientation of the fragments; the pattern in this case being a system of concentric rings, as exemplified by Fig. 2.

While it is very easy, when one knows the structure of the crystal and the wavelength of the rays, to predict the diffraction pattern, it is quite another matter to deduce the crystal structure in all its details from the observed pattern and the known wavelength. The first step is to determine the spacing of the atomic planes from the Bragg equation, and hence the dimensions of the unit cell. Any special symmetry of the space group of the structure will be apparent from space group extinction. A trial analysis may then solve the structure, or it may be necessary to measure the structure factors and try to find the phases or a Fourier synthesis. Various techniques can be used, such as the F2 series, the heavy atom, the isomorphous series, anomalous atomic scattering, expansion of the crystal and other methods.

By such methods, the structures of crystals have been determined and all of them can be shown to possess space structures corresponding to one or another of the 14 Bravais lattices. See Figs. 3 and 4.

Crystal Systems and Crystallography. The field that deals with the geometrical relations between the atomic planes within them is *crystallography*. Some minerals, if broken, will separate along given 'cleavage planes' into polyhedral fragments. Even when powdered, the minute grains will show this characteristic and measurements will indicate the planes to belong to one or another plane family, the members of any one

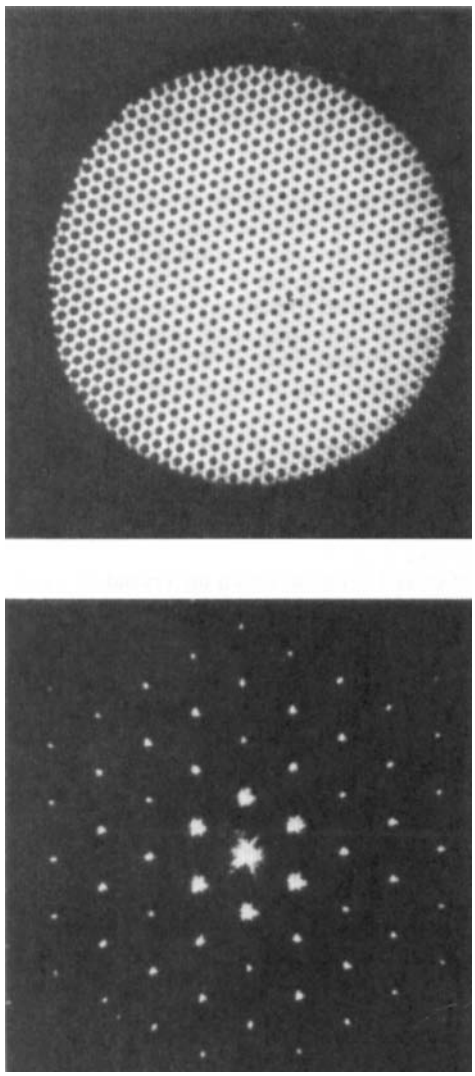

Fig. 1. Types of x-ray patterns of crystals: (**a**) Steel balls in a crystalline lattice; (**b**) Bragg reflections with shape S^2.

Fig. 2. Concentric ring pattern of crystalline materials.

of which are all parallel. It should be stressed, however, that all minerals do not possess cleavage planes for such experimentation.

In most crystal systems each of the more prominent crystal faces belongs to one of three plane-families intersecting along what are called the crystal axes. In the hexagonal system there are four. These may be conveniently used as coordinate axes, X, Y, Z, though they are not generally at right angles. Haüy discovered that if the ratio of the intercepts of two crystals planes on one of these axes is a simple fraction, such as $\frac{3}{5}$, the ratios of the intercepts on the other axes are likewise simple. This suggests that the two intercepts on any one axis are multiples of a common unit. The units are, however, generally different for the different axes, bearing to each other ratios called the axial ratios.

It is more convenient to use the reciprocals of the intercepts. For example, a plane might have intercepts equal to 10,000, 15,000, and 6,000 of the respective units. The reciprocals have the ratios 1/10,000: 1/15,000:1.6,000, which in lowest terms are 3:2:5. These smallest integers are the Miller indices of the family to which this plane belongs, and the family is thus designated (325). The family (201) is parallel to the Y

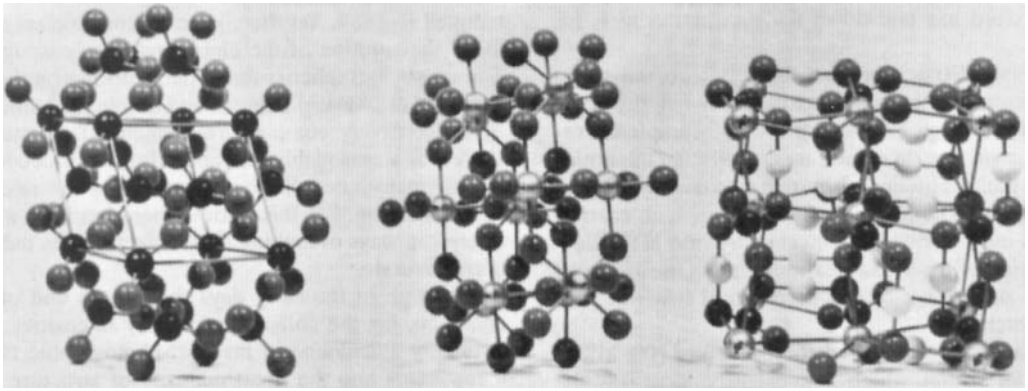

Fig. 3. Computer-generated crystal structure models: (left to right) Beta-quartz, rutile, potassium dihydrogen phosphate (*AT&T Bell Laboratories*).

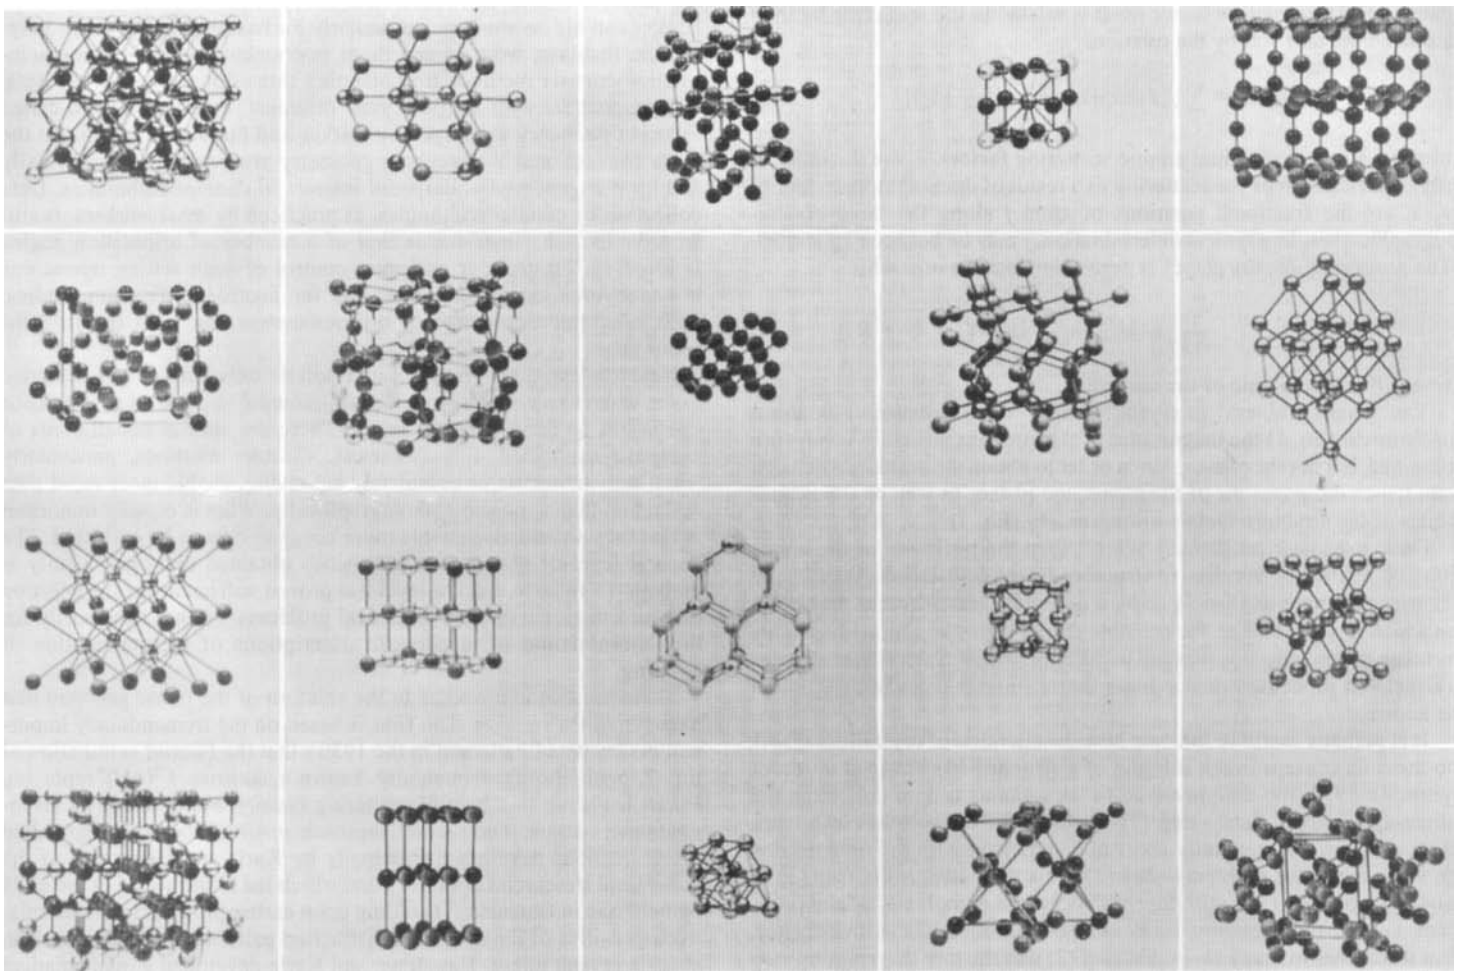

Fig. 4. Computer-generated crystal structure models: (top row, left to right) Cuprite, zinc-blende, rutile, perovskite, tridymite; (second row) Cristobalite, potassium dihydrogen phosphate, diamond, pyrites, arsenic; (third row) Cesium chloride, sodium chloride, wurtzite, copper, niccolite; (fourth row) Spinel, graphite, beryllium, carbon dioxide, alpha quartz. (*AT&T Bell Laboratories*.)

axis but intersects the X and Z axes. (The hexagonal system has four Bravais-Miller indices for each plane-family.)

If the intercept of any plane has a negative value, that is, if it cuts the axes when extended in a direction opposite to that in the standard arrangement, the fact is shown by a bar over the Miller index, e.g., $(2\bar{2}2)$. The eight faces of an octahedron are (111), $(1\bar{1}1)$, $(\bar{1}11)$, $(\bar{1}\bar{1}1)$, $(1\bar{1}\bar{1})$, $(11\bar{1})$, $(\bar{1}1\bar{1})$, and $(\bar{1}\bar{1}\bar{1})$, that is, they all belong to the form (111).

Close study of the angles, indices, and axial ratios long since made it clear that every crystalline substance has a structure built upon a space "lattice" characteristic of the substance. It has been established that this is due to the regular arrangement of the atoms, molecules, or ions composing the substance. As shown by Table 1, the lattice structures of crystals may be classified into 32 symmetry classes (point groups), which are further divided into seven systems. This topic also is discussed under **Mineralogy**.

Practically all minerals are crystalline, although perfect natural crystals are seldom, if ever, found. Because of the laws of crystallography, however, a crystallographer can usually determine the crystal form of a known species from a fragment of the original crystal, provided that at least two of the crystal faces are visible. Crystalline aggregates are said to be cryptocrystalline when the individual particles are proved to have crystalline structure but their crystal faces are exceedingly small or indistinguishable. A mineral is pseudocrystalline if its external form does not correspond with its crystalline structure.

A new structural form has been proposed of *quasicrystals* — designated *shechtmanite* — which are neither crystalline nor completely amorphous. These materials possess a fivefold symmetry of long-range order. Despite

TABLE 1. ELEMENTS OF CRYSTAL SYSTEMS

System	Crystallographic Elements	Essential Symmetry	Number of Point Groups
Cubic, or regular	Three axes at right angles: all equal.	4 triad axes; 3 diad, or 3 tetrad axes	5
Tetragonal	Three axes at right angles: two equal.	1 tetrad axis	7
Orthorhombic or rhombic	Three axes at right angles: unequal.	3 diad axes, or 1 diad axis and 2 perpendicular planes intersecting in a diad axis	3
Monoclinic	Three axes, one pair not at right angles: unequal.	1 diad axis, or 1 plane	3
Triclinic or anorthic	Three axes not at right angles: unequal.	No axes or planes	2
Hexagonal	Three axes co-planar at 60°: equal. Fourth axis at right angles to other three.	1 hexad axis	7
Rhombohedral or trigonal	Three axes equally inclined, not at right angles: all equal.	1 triad axis	5

Pauling's contention that data on these structures can be related to the common phenomenon of "twinning," increasing data indicate that this structural system does exist and has long been ignored because the icosahedral, fivefold symmetry upon which it is based cannot serve as a unit cell of a crystal. The difficulties presented in composing structures based upon icosahedra require also the concept of "tiling," that is, the filling of a three-dimensional space gap with two-dimensional structures or "tiles" while maintaining a periodicity of structure. Penrose of Oxford has laid down the essential criteria for such structures.

Determination of Crystal Structure. The object of a crystal-structure determination is to ascertain the position of all of the atoms in the unit cell, or translational building block, of a presumed completely ordered three-dimensional structure. In some cases, additional quantities of physical interest, e.g., the amplitudes of thermal motion, may also be derived from the experiment. The processes involved in such crystal-structure determinations may be divided conveniently into (1) collection of the data, (2) solution of the phase relations among the scattered x-rays (phase problem)—determination of a correct trial structure, and (3) refinement of this structure.

The data consist of intensities $I(hkl)$, where h, k, and l (the Miller indices represent a vector triplet which conveniently identifies the beam diffracted from a single crystal. In a typical determination, there may be one to two thousand such $I(hkl)$. The intensity is related to the structure factor $F(hkl)$ by the relation.

$$I(hkl) = KF(hkl)F^*(hkl) \tag{1}$$

where K is a known relative factor, and where F^* is the complex conjugate of F. The structure factor itself is related to the scattering by the j atoms in the unit cell by the relation,

$$F(hkl) = \sum_j f_j T_j \exp\,[2\pi i(hx_j + ky_j + lz)] \tag{2}$$

where f_j are the individual atomic scattering factors, T_j are the individual modifications of the scattering as a result of thermal motion, and x_j, y_j, z_j are the fractional positions of atom j along the three crystallographic axes. In a typical determination, j may be between 10 and 60. The *scattering density* $\rho(xyz)$ is derivable from the relation,

$$\rho(xyz) = V^{-1} \sum_{-\infty h,k,l}^{\infty} F(hkl) \exp\,[-2\pi i(hx_j + ky + lz)] \tag{3}$$

where V is the volume of the unit cell.

The "phase problem" in crystallography arises because in the usual experiment (Eq. 1) the magnitudes of the complex structure factors are obtained, but not the phases. Yet in order to obtain the scattering density, and hence the positions of the atoms, the phases as well as the magnitudes of the structure factors are necessary (Eq. 3).

Once the phase problem is solved, then the positions of the atoms may be refined by successive structure-factor calculations (Eq. 2) and Fourier summations (Eq. 3) or by a nonlinear least-squares procedure in which one minimizes, for example, $\sum w(|F_{obs}| - |F_{calc}|)^2$. with weights w taken in a manner appropriate to the experiment. Such a least-squares refinement procedure presupposes that a suitable calculational model is known.

It is perhaps useful to indicate how the attention of crystallographers to these three steps in the solution of a structure has changed in recent years. In 1954, the time involved in the arduous task of collecting the three-dimensional data—step (1)—needed for the solution of a complex problem was generally short in comparison with the time needed to solve the phase problem—step (2). This time involved in step (2) of course depended (and still depends) upon the complexity of the problem, and on the ingenuity, luck, and perseverance of the investigator, but it was true in many cases that step (2) was the rate-determining step in the entire process. This in part was because little attention was paid to detailed refinements—step (3); in 1954, three-dimensional least-squares refinements of complex structures were out of the question computationally, and even Fourier refinements were rare, for on computing systems advanced for those days (e.g., punched-card tabulators, sorters, and primitive electronic computers), a three-dimensional Fourier summation might require forty man-hours. In fact, in 1954 it was usual for the crystallographer to examine the unit cells of a number of related substances and to pick the problem that was crystallographically most favorable (and perhaps soluble from two-dimensional data), even though this problem might not be the one of greatest chemical or physical interest. Ten years later the situation had changed markedly, mainly because of the availability of high-speed computers. It is still true that there are classes of problems where step (2) is rate-determining, but these problems are far more complex than those attempted in 1954. Yet there is an extensive class of problems in which today the solution of the phase problem is straightforward and rapid. The crystallographer is thus often working on the problem of greatest chemical or physical interest, and is able to obtain a solution in feasible time. Relatively complete refinement of structures is now the rule, since it is a reasonably fast and effortless procedure. Thus it turns out that in many crystallographic problems the rate-determining step is data collection. For this reason, there has been a dramatic increase in interest in ways of making data collection less tedious, more rapid, and more accurate.

Although in the early days the Braggs and others used ionization chambers for the collection of x-ray intensities, these methods were gradually abandoned in favor of photographic film techniques. Until a few years ago the great majority of structure determinations were based on photographically recorded intensities, usually visually estimated. This process is a slow one: the typical time involved in the collection and estimation of a data set of two thousand intensities is perhaps six to eight weeks. Collection of intensity data from protein crystals is far more challenging and time-consuming, both because the number of data to be collected is far greater and because the crystals are unstable and rapid collection is thus desirable. For these reasons, Harker and his co-workers, particularly Furnas, then at Brooklyn Polytechnic Institute, were among those instrumental in developing scintillation-counter methods for collecting three-dimensional x-ray data. Diffractometers with single-crystal orienters, based on the so-called Eulerian geometry developed by Harker and Furnas, as well as on the more conventional Weissenberg geometry are available commercially and have engendered widespread interest in counter techniques. Data collection by counter techniques, as practiced by most workers, is still an arduous task, since the setting of a number of orientation angles is involved. Program or computer control of such setting operations is an obvious extension. Especially for neutron diffraction studies, such programmed control of diffractometers has been the rule for some time.

Nevertheless, a programmed unit will do only what it was designed to do, whereas a computer can be programmed to perform new tasks or operations as they seem necessary. There are several installations of computer-controlled diffractometers. Counter methods, particularly when

semiautomatic or completely automatic, enable more rapid data collection than is possible photographically. What is equally important is that they should also enable more accurate data to be collected. The general level of accuracy of intensities obtained photographically is perhaps 15 to 20%. Such a level has proved sufficient for the solution of conformational or stereochemical problems, but not necessarily for the determination of meaningful descriptions of thermal motion or bonding.

There are two approaches to the solution of the phase problem that have remained in favor. The first is based on the tremendously important discovery of Patterson in the 1930s that the Fourier summation of Eq. 3, with the experimentally known quantities $F^2(hkl)$ replacing $F(hkl)$ leads not to a map of scattering density, but to a map of all interatomic vectors. The second approach involves the use of so-called direct methods developed principally by Karle and Hauptman of the U.S. Naval Research Laboratory and which led to the award of the 1985 Nobel Prize in Chemistry. Building upon earlier proposals that the relative intensities of the spots in a diffraction pattern contain information about a crystal phase. Hauptman and Karle developed a mathematical means of extracting the information. A fundamental proposition of their direct method is that if three intense spots in the pattern have positions whose coordinates add up to zero, their relative phases will cancel out. Computations done with many triads of spots yield probable phases for a significant number of diffracted waves and further mathematical analysis leads to a likely solution for the structure of the molecule as a whole.

The *Patterson function* has been the most useful and generally applicable approach to the solution of the phase problem, and over the years a number of ingenious methods of unraveling the Patterson function have been proposed. Many of these methods involve multiple superpositions of parts of the map, or "image-seeking" with known vectors. Such processes are ideally suited to machine computation. Whereas the great increase in the power of x-ray methods of structure determination in the past few years has come simply from our ability to compute a three-dimensional Patterson function, it is reasonable to expect that, as machine methods of unraveling the Patterson function are developed, this power will increase many fold.

Step (3), the refinement of crystal structure, continues to enjoy a considerable amount of interest. Reasonably complete refinement is routine these days, owing in large measure to the availability of suitable computers. For reasons that are both practical and mathematically sound, the least-squares approach to refinement has gained favor over the successive structure-factor-Fourier approach. Yet the computational problems often tax this generation of computers. If one assigns a single isotropic thermal parameter to each atom, then there are four parameters, three positional and one thermal, to be determined for each atom. In the least-squares procedure, if one stores the upper right triangle of the normal-equations' matrix, then $\frac{1}{2}N(N+1)$ elements are required, where N is the number of variables. In a machine with a memory of 32,000 words, a practical limit is reached at about $N = 200$, if one wishes to keep the rest of the program in core. Thus refinement of a 50-atom problem often taxes the memory capacity of the machine, and for larger problems special computational or mathematical tricks are needed. One of these tricks is to make use of known features of the structure or the thermal motion to reduce the number of parameters. But, even with increased numbers and more rapid availability of data, computerized solutions to crystallographic problems still suffer from a degree of uniqueness. Programs written to operate on one machine must often be extensively revised to be used on another. An international group of workers at the National Resource for Computation in Chemistry at the Lawrence Berkeley Laboratory is trying to overcome this problem of interchangeability by writing a program designed to run on any medium or large sized computer. When completed, the program will allow a crystallographer, armed only with experimental data and a computer, to determine the structure of any crystal without having to write special programs.

Crystal Growth. The direct growth of an ideal and perfect crystal is difficult except at very high supersaturations because of the difficulty of nucleating a new surface on a completed surface of the crystal. But, if there is a screw dislocation present, it is not necessary to start a new surface, and growth proceeds in a spiral fashion by the accretion of atoms at the edge of growth steps. The resultant growth spirals have been observed, and it is believed that most crystals grow in this manner. See Fig. 5. But spiral growth is not the only mechanism that enables crystal growth at fast rates. Gilmer, in particular, has employed computer simulation models in studies of crystal growth and has demonstrated that, among other influences, temperature and impurity levels have decisive effects upon growth rates. Again, since different crystal faces have different kinetic properties, the particular crystal plane exposed to growth will also be a partial determinant of growth rate.

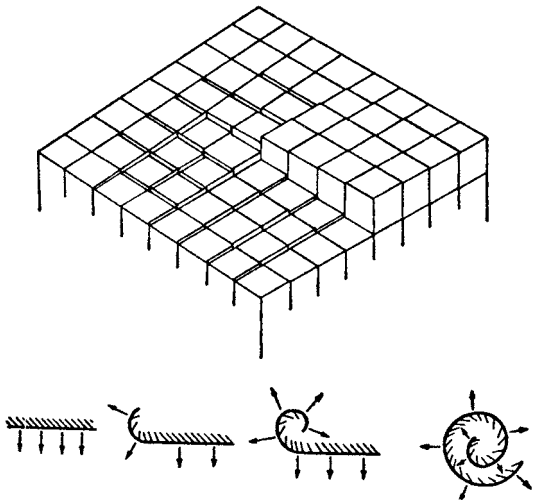

Fig. 5. Highly schematic representation of crystal growth. (*F.C. Frank.*)

In modern technology based upon solid state chemistry and physics, much emphasis is placed upon the availability of elements and compounds in single-crystal form. Over the past twenty-five years a highly sophisticated technology has developed in this area. From the relatively simplistic growth of ammonium and potassium dihydrogen phosphates (ADP and KDP) from saturated solutions for transducer elements, a level has been obtained at which pure metals (Cu, Pb, Al, Ag, Fe, etc.), a semi-metals (Si, Ge, As, etc.), and compounds (GaAs, InAs, InSb, InP, etc.) are available and even essential in large single crystal form to the electronics industries. Synthetic gems (rubies, spinels, sapphires, emeralds, and zircons) are single crystals of aluminum, beryllium, and zirconium silicates or oxides with controlled impurity levels of transition elements.

Growth of such single crystals can follow several techniques, with thermodynamic constraints dictating the technique for any particular material: crystallization by cooling a supersaturated solution of a compound in a high-temperature flux; crystallization by dropping powder through an intense flame onto a seed pedestal, known as the Verneuil technique (see Fig. 6); crystallization by pulling a "seed" crystal from the surface of a liquid melt, known as the Czochralski method (see Fig. 7); crystallization by lowering a melt through a small, controlled thermal gradient, known as the Stockbarger technique (see Fig. 8); crystallization by zone-melting, known as the Pfann method (see Fig. 9); and crystallization by the vapor-phase approach (see Fig. 10). All of these procedures, however, require three essential ingredients: (1) A good "seed" crystal from which spiral and sometimes oriented growth can occur and develop; (2) highly precise operational conditions-movement of fractions of a millimeter, or temperature variations of 0.5 °C per hour; and (3), as previously indicated, materials of a specific impurity level. Given these conditions, single crystals can be grown in large quantities-ranging from the multimillion carat operations of Linde (United States) and Djevaherdijian (Switzerland), using the Verneuil technique, to the multikilo manufacture of single crystal silicon by Texas Instruments Incorporated (United States), employing the Czochralski and zone melt methods, and including a 27-kilogram single crystal of dislocation-free silicon by the Kayex Corporation (United States) grown by a modified Czochralski approach.

See also **Semiconductors**.

Dislocation in Crystalline Solids. This type of imperfection in a crystalline solid is generated as follows: A closed curve is drawn within the solid, and a cut made along any simple surface which has this curve as boundary. The material on one side of this surface is displaced by a fixed amount called the Burgers vector relative to the other side. Any gap or overlap is made good by the addition or removal of material, and the

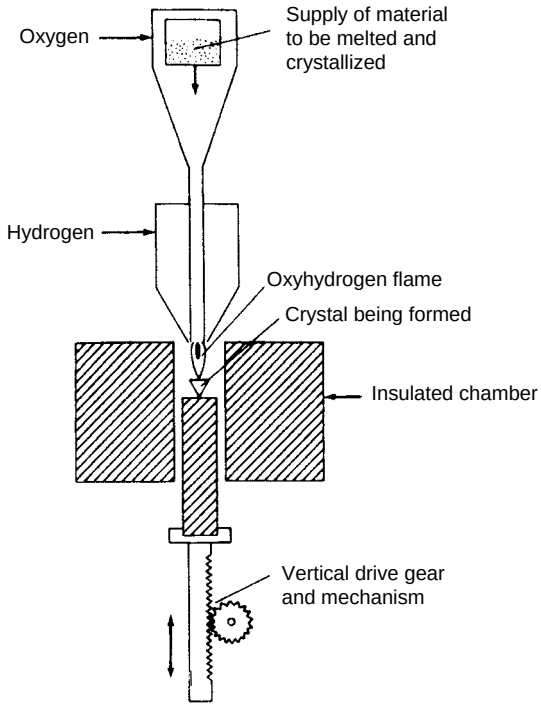

Fig. 6. Verneuil technique for growing crystals.

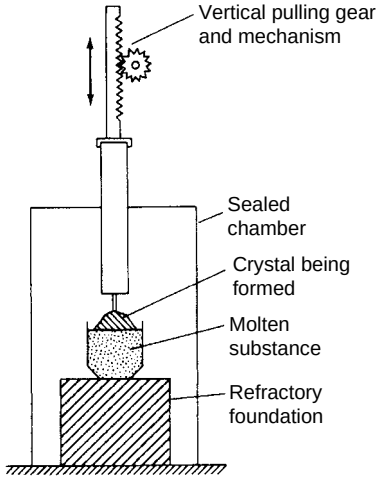

Fig. 7. Czochralski method for growing crystals.

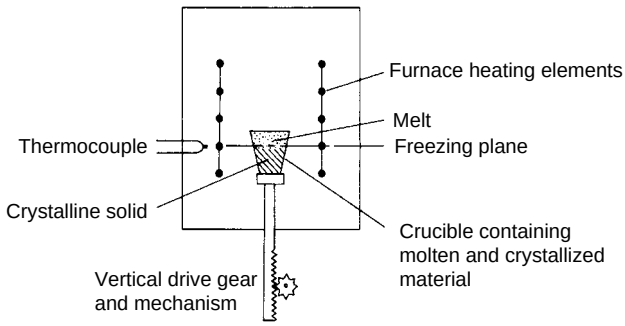

Fig. 8. Stockbarger technique for growing crystals.

two sides are then rejoined, leaving the strain displacement intact at the moment of rewelding, but afterwards allowing the medium to come to internal equilibrium. If the Burgers vector represents a translation vector of the lattice, the weld is invisible, and the dislocation is characterized only by the original curve, or dislocation line and by the Burgers vector.

A dislocation line may only terminate at the surface of the crystal. The energy of a dislocation is largely stored as strain in the surrounding lattice. The important property of a dislocation is its ability to move quite easily through the lattice, and hence to allow the rapid propagation of slip. The general dislocation defined above usually separates into its components, edge and screw dislocations, which may be treated as rather stable entities in the theory. Direct evidence for the existence of dislocations is the observation of dislocation networks in crystals of silver bromide, and, for their motion, from the spiral growth patterns in crystals.

In recent years high-resolution electron microscopes have been used to study dislocations and their movements in thin crystals. This is possible in both metals and nonmetals. Other techniques that have been applied successfully are field ion microscopy and x-ray microscopy. Dislocations are important in determining the mechanical and electrical properties of solids, and play an important part in solid state physics. The density of dislocations (i.e., the concentration of dislocation lines), for example, is believed to vary from about 100,000,000 per square centimeter in good natural crystals, through 1,000,000,000 in good artificial crystals up to about 1,000,000,000,000 in cold-worked specimens. These estimates are based on the energy stored by cold work, on x-ray analysis, and on measurements of electrical resistivity. Among the various types of dislocation are the *edge dislocation*, which is defined as having its Burgers vector (line of displacement) normal to the line of the dislocation. An edge dislocation may be thought of as caused by inserting an extra plane of

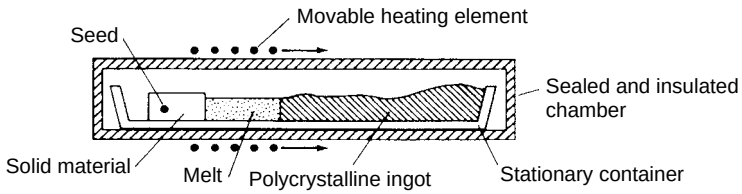

Fig. 9. Zone-melting or Pfann method for growing crystals.

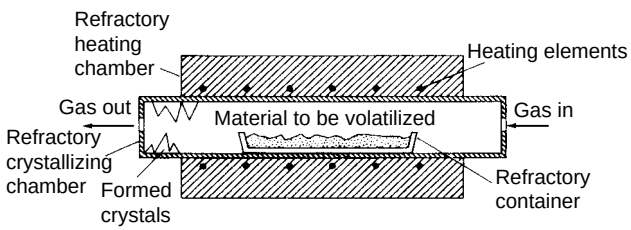

Fig. 10. Crystallization by the vapor-phase approach.

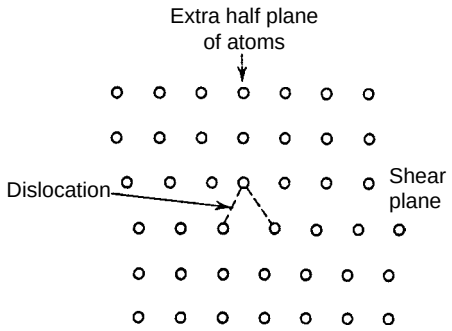

Fig. 11. Atomic arrangement in an edge dislocation.

atoms terminating along the line of the dislocation (Fig. 11). For example, if the dislocation were along the Z-axis and its Burgers vector along the X-axis, then one might think of an extra half plane of atoms being inserted at the surface $x = 0$, $y > 0$. Such a dislocation would be of positive sign. An edge dislocation may move easily only parallel to its Burgers vector, i.e., in its slip plane.

The *screw dislocation* has its Burgers vector parallel to the line of the dislocation. In a screw dislocation, the atomic planes are joined together in such a way as to form a spiral staircase, winding round the line of the dislocation (Fig. 12). A screw dislocation is capable of easy movement in any direction normal to itself. The growth spirals formed in crystal growth appear where such dislocations intersect the surface. Edge dislocations of the same sign repel each other along the line between them, but are most stable when arranged vertically above each other. Edge dislocations of opposite signs attract one another, but otherwise prefer to lie so that the line between them makes an angle of 45° with their slip planes. Screw dislocations of opposite sign attract, of like sign repel.

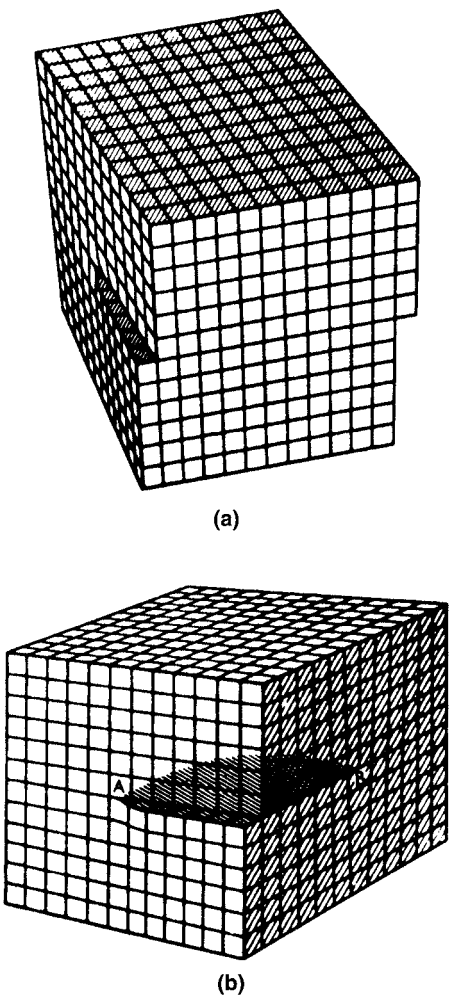

Fig. 12. (**a**) Simple type of screw dislocation; (**b**) both screw and edge dislocation along the arc from A to B.

Dislocation Line. The curve separating displaced and undisplaced positions of a crystal, and thus at the center of a dislocation, is termed the dislocation line. Within a distance of one or two lattice constants of the dislocation line the atoms are displaced by an amount more than can be represented fairly as a strain. A screw location may have a substantial hole down the dislocation line, through which impurity atoms may diffuse.

Dislocation Climb. This is a type of dislocation motion, differing fundamentally from slip, associated with the edge components of dislocations. In climb, an edge dislocation moves in a direction perpendicular to its slip plane as atoms are either added to or taken away from the extra plane of the dislocation. The motion of atoms to and from the dislocation is accomplished by vacancy movements. If an atom in the plane next to the edge jumps out of its position and attaches itself to the extra plane, as indicated in the accompanying figure, a vacancy is created which can then diffuse off into the lattice. Repetition of this process over and over will cause the extra plane to grow in size and, if this occurs, the process is said to be negative climb. On the other hand, if vacancies diffuse up to the extra plane of the dislocation and remove atoms from it, the plane grows smaller in size and positive climb is said to occur.

Dislocation climb only becomes of practical significance at elevated temperatures because of its dependence upon vacancies whose number and mobility depend very strongly on the temperature. Dislocation climb is important in high temperature creep and recovery phenomena. See Fig. 13.

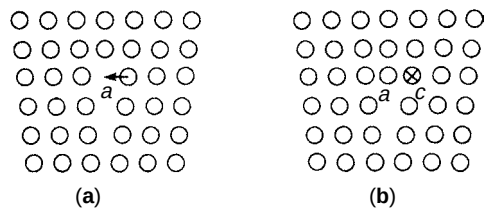

Fig. 13. Negative climb of an edge dislocation.

Crystal Slip. This is the process by which a crystal undergoes plastic deformation, as a result of which one atomic plane moves over another. Slip is believed to occur through the movement of dislocations. The total deformation of a given crystal is the sum of many small lateral displacements in parallel crystallographic planes of a given family. Moreover, each slip plane becomes more resistant to further deformation than the remaining potential slip planes.

Cross-Slip. This is slip that occurs simultaneously on several slip planes having the same slip direction. See Fig. 14. This type of plastic deformation is normally associated with the movement of screw dislocations. Screw dislocations can move on any slip plane that passes through the dislocation. This is a result of the fact that the slip plane of a dislocation is that plane which contains both the dislocation and its Burgers vector, and the fact that the Burgers vector of a screw dislocation lies parallel to the dislocation itself.

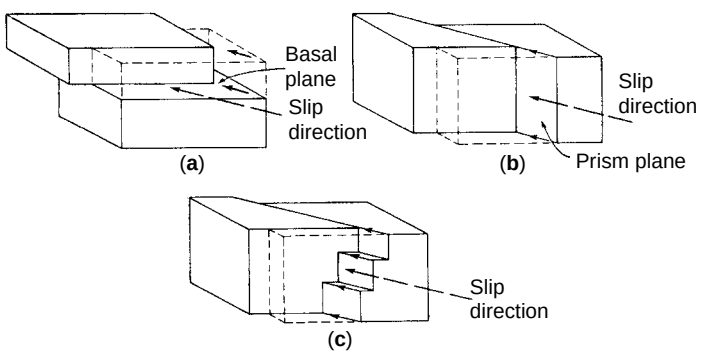

Fig. 14. Schematic representation of cross-slip in a hexagonal metal: (**a**) slip on basal plane; (**b**) skip on prism plane; (**c**) cross-slip on basal and prism planes.

Quasicrystals

The existence of quasicrystals was discovered by the Israeli scientist, D. Shechman, in the early 1980s. After years of experimentation, the first practical application for such materials was announced in the early 1990s in connection with the development of a nonstick, abrasion-resistant coating for cookware. They appear to be good candidates for a number of tribological uses because of their excellent wearability and abrasion resistance. Patents along these lines have been granted to the Centre National de la Recherche Scientifique in France. Researchers targeted two compounds with the nominal composition (atomic percent) of $A1_{65}Cu_{20}Fe_{15}$ (designated as alloy A) and $A1_{64}Cu_{18}Fe_8Cr_8$ (designated as alloy B). Powders were prepared by mechanically grinding ingots to a mesh size ranging from 20 to 75 micrometers (0.0008 to 0.003 in.) and were thermally sprayed onto "soft" aluminum alloy, pure copper, and low-carbon steel substrates using flame, supersonic, and plasma-arc spraying. The deposited materials consist of a mixture of quasicrystals and crystalline phases. Alloy A contains about 70 percent icosahedral phase, while alloy B contains about 70 percent quasicrystalline (icosahedral plus decagonal) phases. An icosahedron is a polygon having 20 faces and a decagon is a polygon having ten angles and ten faces.

As pointed out by Stephens and Goldman (State University of New York at Stony Brook), "Quasicrystals are neither uniformly ordered like crystals nor amorphous like glasses. Many features of quasicrystals can be explained, but their atomic structure remains to be described fully." See also **Aluminum Alloys and Engineered Materials**.

CRYSTAL DETECTOR. A device consisting of a "cat's whisker" bearing on a semiconducting crystal, used in early radio sets and in microwave receivers. It depends for its action on the rectifying properties of the point contact, just as in the point contact transistor.

CRYSTAL (Face-Centered). A type of crystal structure in which atoms occupy the corners and centers of the faces of a cube or other parallelepiped. The face-centered cubic structure is *close-packed*.

CRYSTAL FIELD THEORY. A theory developed in the early 1930s in research on magnetism by Bethe, Van Vleck and others. It applied particularly to the transition metal ions, and is therefore conveniently treated by reference to those ions.

A transition metal ion in a complex or compound is considered to be subject to the electrostatic field of the molecules and ions in its neighborhood, particularly by those constituting its nearest neighbors. In the compounds to which the theory applies, the only nearest neighbors important to the theory are either negative ions, or molecules such as NH_3 which have unshared electron pairs and which orient themselves so that the negative end of the electron-pair dipole is directed toward the transition metal ion. The effect of these negative ions or negatively oriented dipoles (which we shall hereafter call ligands, with the understanding that ligand field theory is a later development of crystal field theory) is to produce a negative field about the positive transition metal ion.

In the absence of this negative field, the *d*-electrons of the central ion have orbitals of equal energy, i.e., degenerate orbitals, but the field of the ligands affects the energies of these orbitals to different degrees. To show how this effect arises, consider the example chosen by Griffith and Orgel. This is the regular octahedral complex MX_6, where M is a metal ion of the first transition series of the elements (see **Periodic Table of the Elements**), and X is a ligand such as H_2O, NH_3 or Cl^-.

The five 3*d* orbitals of M have the forms indicated in Fig. 1, in which the coordinate axes lie along the MX bond directions. It is clear from the figure that the d_{z^2} and $d_{x^2-y^2}$ orbitals have substantial amplitudes in the directions of the ligands but that the orbitals d_{xy}, d_{yz}, and d_{zx} tend to avoid them. Hence the energy of an electron in the d_z^2 or $d_{x^2-y^2}$ orbitals will be substantially raised by the repulsive field of the ligands,

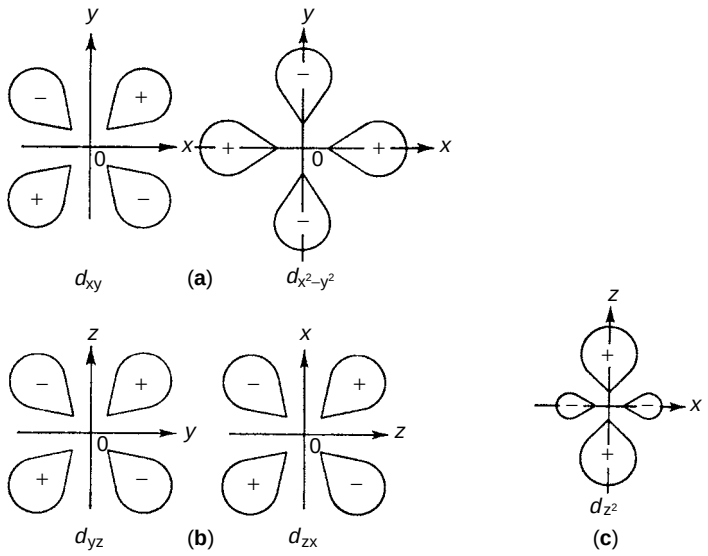

Fig. 1. Cross section of the five *d* orbitals, chosen in real form.

TABLE 1. *d*-ELECTRON ARRANGEMENTS IN OCTAHEDRAL COMPLEXES

Number of *d* Electrons	Arrangement in Weak Ligand Field		*N*	Arrangement in Strong Ligand Field		*N*	Gain in Orbital Energy in Strong Field
	t_{2g}	e_g	t_{2g}	e_g			
1	↑	—	0	↑	—	0	0
2	↑↑	—	1	↑↑	—	1	0
3	↑↑↑	—	3	↑↑↑	—	3	0
4	↑↑↑	↑	6	↑↓↑↑	—	3	Δ
6	↑↓↑↑	↑↑	10	↑↓↑↓↑↓	—	6	2Δ
7	↑↓↑↓↑	↑↑	11	↑↓↑↓↑↓	↑	9	Δ

9	↑↓↑↓↑↓	↑↓↑	16	↑↓↑↓↑↓	↑↓↑	16	0

N Number of distinct pairs of electrons with parallel spin.

whereas the energy of an electron in the d_{xy}, d_{yz}, or d_{zx} orbitals will be comparatively little affected. Furthermore, it is obvious from symmetry that the degeneracy of the last three orbitals is maintained in the octahedral complex and it can be shown by group theory that the d_{z^2} and the $d_{x^2-y^2}$ orbitals also remain degenerate. Consequently the five *d* orbitals split into a lower group of three and an upper group of two, the two groups being usually designated as t_{2g} and e_g respectively (or sometimes as γ_5 and γ_3, and as $d \in$ and $d\gamma$ respectively).

In tetrahedral complexes it can be shown similarly that the *d* orbitals are again split into groups of three and two, respectively, but now the doubly degenerate orbital is lower. In all other important cases the degeneracy of the *d* orbitals is reduced even further.

In order to understand the electronic structure of an octahedral complex and the optical transitions it can undergo, it is necessary to appreciate the principles determining the distribution of the *d* electrons among the t_{2g} and e_g orbitals. Let us begin by considering the ground state. Two separate tendencies are at work. The first is the tendency for the electrons to occupy, as far as possible, the orbitals of lowest energy in the ligand field. The second is for the electrons to go into different orbitals with their spins parallel, since this gives a lower electrostatic repulsive energy and a more favorable exchange energy. Let us now see how these ideas apply to an octahedral complex containing *n* 3*d* electrons.

The ion $[Ti(H_2O)_6]^{3+}$ has one *d* electron. In the ground state this will obviously occupy one of the t_{2y} orbitals. A transition is possible in which this electron is transferred to one of the e_y orbitals, and this occurs at 20,400 cm^{-1}. (The intensities of such transitions are low — $\epsilon_{max} \approx 10$ — as they are symmetry-forbidden.) The converse situation arises in the hydrated copper(II) ion which has nine *d* electrons. In this ion the vacancy in the *d* shell is one of the e_y orbitals. This vacancy can be filled by exciting an electron from one of the t_{2g} orbitals, giving rise to a transition at about 12,500 cm^{-1}. However, the ion $[Cu(H_2O)_6]^{2+}$ is strongly distorted in its ground state so that most of the degeneracy of the t_{2g} and e_g orbitals is removed and there is more than one transition in this region. From these two examples we see that the splitting between the t_{2g} and the e_g orbitals may be quite large, being usually in the range 20–50 kcal $mole^{-1}$.

It is only when we come to consider complexes with several *d* electrons that complications arise. If there are only two or three *d* electrons, both the above-mentioned tendencies can be satisfied simultaneously by placing the electrons in different t_{2g} orbitals with their spins parallel. However, when there are more than three *d* electrons this is no longer possible. If there are 4–7*d* electrons we then have the choice either of putting as many as possible into the low-energy t_{2g} orbital or distributing them so as to maintain a maximum number of parallel spins. This is illustrated in Table 1.

The former choice will be favored if the orbital separation Δ is large, and the latter will be realized if Δ is small. The value of Δ depends primarily on the nature of the ligand and the charge on the ion, and the following generalizations can be made for the first transition series. (1) For hydrated bivalent ions Δ falls in the range 7,500–12,500 cm^{-1}. (2) For hydrated tervalent ions Δ falls in the range 13,500–21,000 cm^{-1}. (3) The common ligands can be arranged in a sequence so that Δ for their complexes with any given metal increases along the sequence. A shortened series is I^-, Br^-, Cl^-, F^-, H_2O, oxalate, pyridine, NH_3. ethylenediamine, NO_2^-, CN^-. Finally, Δ for the compounds of the second and third series is 40–80% larger than for corresponding compounds of the first series.

With these considerations in mind let us consider in turn the two extreme possibilities, known respectively as the "strong-field" and the "weak-field" case. If Δ is very large the tendency for electrons to go into separate orbitals will be outweighed by their tendency to occupy the t_{2g} orbitals (as against the e_g orbitals) in circumstances where these two tendencies conflict. In the strong-field case, therefore, a complex with up to six *d* electrons will have all these in t_{2g} orbitals with the maximum number of unpaired spins consistent with the restriction to the t_{2g} orbitals. As examples we may take the hexacyanoferrates(II) and (III) which possess six and five *d* electrons, respectively, all in t_{2g} orbitals with the maximum number of unpaired spins consistent with the restriction to the t_{2g} orbitals. As examples we may take the hexacyanoferrates(II) and hexacyanoferrates(III) which possess six and five *d* electrons respectively all in t_{2g} orbitals. The former has no unpaired electrons and the latter one. The next four electrons will then enter the e_g orbitals; the first two will go into different e_g orbitals with their spins parallel as in the octahedral complexes of Ni^{2+}. In Co^{2+} there is just one e_g electron.

The complex $[Co(NH_3)_6]^{3+}$ provides a good example of the strong-field case. The ground state is $(t_{2g})^6$ and the transitions observed at the longest wavelengths involve taking one of these electrons and putting it in an e_g orbital. According to the choice of the orbitals involved the final state may be one of the two triply degenerate states, and the bands associated with the two transitions have been observed for a number of d_6 complexes in each of the three transition series. (The separation between the bands is not in very good agreement with theory, however, so that it is difficult to obtain a reliable value of Δ for such cobalt(III) complexes. The reasons for this are not fully understood at present.)

The weak-field case is that in which the separation Δ is not large enough to overcome the tendency of the *d* electrons to go into different orbitals with their spins parallel. For example, in the hydrated manganese(II) ion the five *d* electrons each occupy one of the five *d* orbitals; this is because the separation Δ is insufficient to break up the highly stable half-filled shell in which all the electron spins are parallel. The same is true of $[Fe(H_2O)_6]^{3+}$ and of the hydrated iron(II) ion, which has six *d* electrons, the extra one being in one of the t_{2g} orbitals. It may be noted again that, only in those complexes containing four, five, six, or seven *d* electrons, is there an important distinction between the strong- and the weak-field cases; if there are one, two, or three *d* electrons, they will necessarily occupy t_{2g} orbitals, while if there are eight or nine, the vacancies in the *d* shell will occur in the e_g orbitals in both the strong- and the weak-field case.

CRYSTAL FILTER. See **Filter (Communication System)**

CRYSTAL HABIT. The external shape of a crystal, which depends on the relative development of the different faces, as well as upon the interfacial angles characteristic of the crystal.

CRYSTAL (Homometric Pairs). Two crystal structures having the same x-ray diffraction pattern. This is possible because, basically, a diffraction pattern depends only on the relative vector distances between the atoms in the lattice, not on their absolute positions in space.

CRYSTAL (Isomorphous). One of two or more crystals which are similar in crystalline form and in chemical properties and are related in

chemical composition in that one or more of the atoms and radicals in one are of similar chemical type to the corresponding atoms or radicals in the other. Usually, one or more of their other atoms or radicals are identical.

CRYSTALLIZATION. Crystals are formed (1) from solution, (2) from fusion, and (3) by sublimation.

The formation of crystals from solution, starting with an unsaturated solution, takes place when a solution is evaporated or cooled below the saturation point, except as retarded by supersaturation. Supersaturation is prevented by the addition of seed crystals of the substance. Since, in the case of the majority of soluble substances, solubility increases with increase of temperature cooling below the saturation point favors the formation of crystals. In very few cases, such as sodium sulfate above 32.4 °C, calcium sulfate (slightly soluble), calcium hydroxide (slightly soluble), solubility decreases with increase of temperature, and the above statement would not apply. A case of wide scope and great importance is that of crystal formation by precipitation upon mixing two solutions. Actually, this is the same as for substances of greater solubility, since the substance precipitated is first formed in solution and the excess above the saturation point separates as precipitate. As a rule the crystals are larger and more perfect the slower their growth. Conversely, when small crystals are desired, rapid stirring and quick cooling are practical. The smaller the crystals of a given substance, the purer the material generally is. Small crystals may be increased in size by allowing them to stand in the mother liquor before separation.

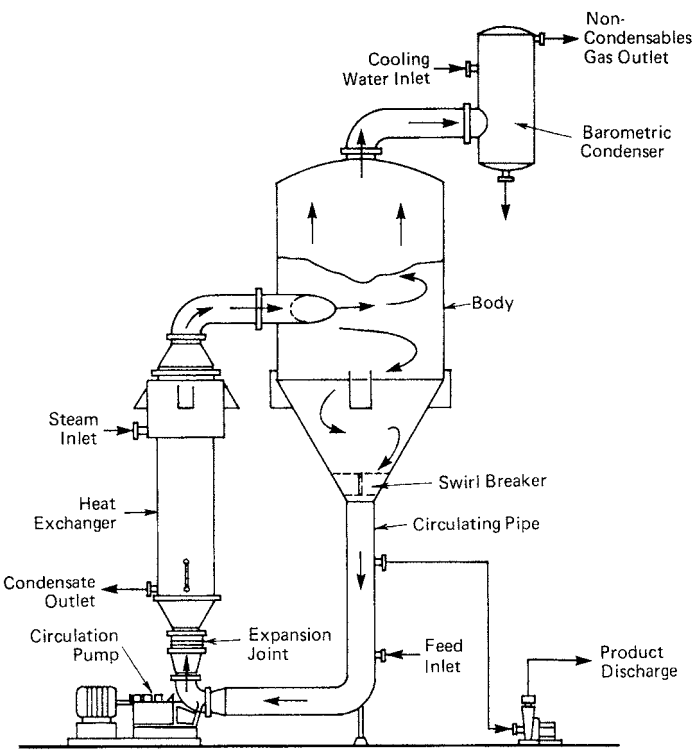

Fig. 1. Forced-circulation evaporative crystallizer.

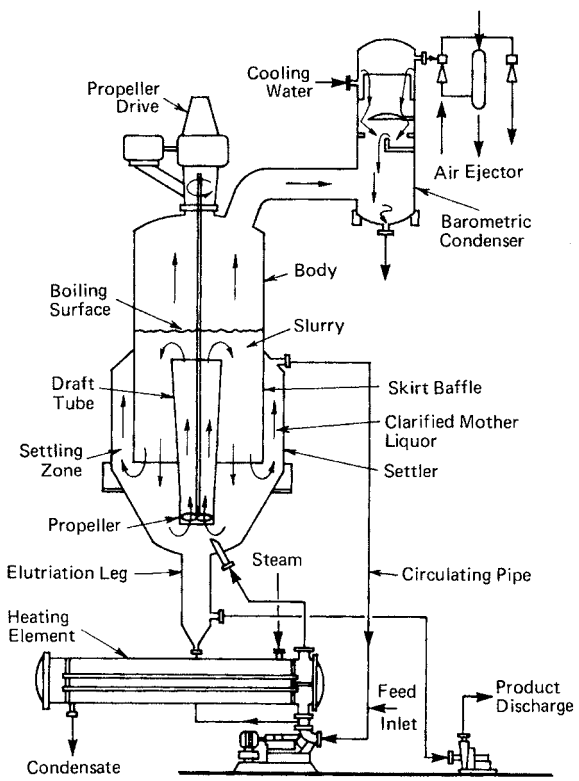

Fig. 2. Draft-tube baffle crystallizer.

An industrial forced-circulation evaporative crystallizer is shown in Fig. 1. Sizes range from 18 inches (~46 centimeters) to over 42 feet (12.6 meters) in diameter, with no inherent limit to the size of the vessel. Slurry is moved by the circulation pump through the heat exchanger, where it is subjected to a temperature rise of 2 to 10 °F. The heated liquor is discharged tangentially into the body at a point sufficiently far beneath the surface so that the liquor entering tangentially is just at the boiling point for the liquid depth at which it is submerged. As the liquid rotates around the body and rises toward the surface, it starts to boil, and this boiling induces a secondary circulation which creates a spinning toroid of fluid within the body. Depending on the location of tangent inlet with respect to the cone, this toroidal circulation can result in considerable secondary circulation and agitation within the body of the vessel. When properly designed, this type of vessel is capable of producing a smooth boiling action with relatively small amounts of salt being deposited on the walls, while still maintaining a suitable suspension of product crystals within the boiling zone and in the lower part of the vessel. Crystalline materials produced in this type of equipment include sodium carbonate, sodium sulfate, and sodium chloride. Operating cycles of this equipment between washouts to remove salt growth from the walls of the body or from the heat exchangers normally range from 30 to 90 days.

To achieve some control of the number of fine particles within the crystallizer body, and thereby increase the overall particle size, it is necessary to selectively remove the fine particles so that they can be destroyed by the action of heat or dilution. A draft-tube baffle crystallizer of the type shown in Fig. 2 achieves these objectives. A body of growing crystals is suspended by the circulation flowing up the draft tube from the propeller shown close to the bottom of the vessel. From the areas surrounding this body of circulated slurry, a stream is removed at relatively low velocity so that gravitational settling will produce a separation between the product-size crystals and relatively fine crystals, which are removed with the clarified mother liquor leaving by the circulating pipe. In the draft-tube baffle crystallizer, both the velocity of the liquor in the settling zone and the quantity of liquor removed by the circulating pump are important to insure that the proper end-product size is achieved and that reasonable stability in particle size is obtained. The equipment is used to crystallize potassium chloride, ammonium sulfate, and other relatively fast-growing inorganic salts.

The foregoing descriptions cover only two of several industrial crystallizer configurations.

The formation of crystals from fusion takes place when the melted substance is cooled sufficiently slowly near and below the fusion point. If the cooling is rapid the fusion may result in the formation of an undercooled liquid of rigidity corresponding to a solid. Glasses, whether artificial, such as glass, vitreous enamels, and slags, or natural, such as vitreous rocks and minerals, e.g., obsidianite, are undercooled liquids. Rocks and minerals that have cooled sufficiently slowly from fusion form crystals, for example, granite. An important method of forming pure crystals is zone melting.

The formation of crystals by sublimation takes place when the vapor of a substance is condensed as a solid without passing through the liquid phase in so doing. This occurs when the temperature of the condenser is below that of the melting point of the substance.

The heat of crystallization is in amount the same as the heat of solution of a given substance but of opposite sign.

CRYSTALLOBLASTIC. Designating the textures of metamorphic rocks resulting from recrystallization under differential and directed pressures and high viscosity.

CRYSTALLOGRAM. The x-ray diffraction pattern of a crystal, whence the crystal structure may be obtained.

CRYSTALLOID. See **Colloid System**.

CRYSTAL (Mixed). A crystal consisting of two or more chemical compounds, which may have the same positive radical or the same negative radical, and which, in their pure form, are isomorphous, i.e., have the same crystal form.

CRYSTAL OSCILLATOR. This device is a precise mechanical resonator and frequency generator. The need for a stable, accurate, and low-cost frequency generator for the precise control of commercial radio and other higher communication frequencies led to the development of piezoelectric resonators, notably quartz crystals, for a wide variety of applications. The quartz crystal has become highly developed as a frequency standard for timekeeping and as a time-signal generator. See also **Oscillator**; and **Piezoelectric Effect**.

Piezoelectricity was discovered by the Curie brothers in 1880. The term *piezo* is derived from the Greek word meaning "to press." The effect causes a crystal to exhibit electrical polarity when the crystal is subjected to mechanical pressure. Conversely, the crystal is physically deformed when subjected to an electrical potential. Specifically, piezoelectricity is a property of nonconducting solids that have a crystal lattice that does not have a center of symmetry.

Quartz, tourmaline, and rochelle salts and such synthetic crystals as ethylene diamine tartrate (EDT), dipotassium tartrate (DKT), and ammonium dihydrogen phosphate (ADP) have varying suitability as piezoelectric elements. Tourmaline, an expensive material used mainly in hydrostatic pressure-measuring devices, is more durable than quartz and, for a given frequency, normally is more rugged than quartz. Rochelle salt has a greater piezoelectric effect than any other crystal but has the disadvantage of a greater sensitivity to temperature change than quartz. EDT has an advantage over quartz when used in frequency-modulated oscillators because of the wide gap between its resonant and antiresonant frequencies.

All piezoelectric crystals should have a good temperature coefficient, that is, should show as little change in resonant frequency as possible under large variations in temperature. Ideally, the piezoelectric constant of proportionality between the mechanical and electrical variables must be the same for both direct (pressure-to-electricity) and converse effects.

Natural quartz crystal and new synthetic quartz crystal have been found best to meet the properties required of a piezoelectric element. Quartz

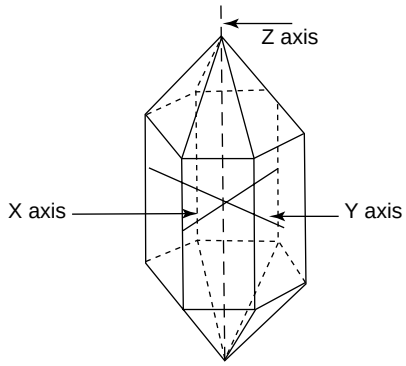

Fig. 1. Principal axes in a quartz crystal.

is hard (7 on Mohs' scale as compared with a diamond, which is 10) and is relatively abundant and stable. Because of the anisotropic structure of quartz, cutting a crystal in different orientations makes it possible to obtain crystals for the widest range of applications, including frequency control, filters, resonators, and electromechanical transducers. Each of these uses depends on the orientation of the crystal cut with respect to the crystallographic axes. As shown in Fig. 1, the principal axes in quartz are identified as the optic (Z), the mechanical (Y), and the electrical (X) axes. By use of polarized light and x-ray diffraction techniques, the various axes may be properly located, permitting a crystal plate to be cut from the quartz with the performance characteristics desired. After cutting and extensive processing, the crystal plate is mounted at the nodal points of its normal vibration. These points, which also serve as electrical connecting points, allow the crystal to vibrate freely with a minimum of damping. Finally, the mounted crystal is hermetically sealed in a dry inert atmosphere within a crystal holder.

A stability of 1 part in a billion is routinely possible by the use of proportional ovens that can regulate the crystal temperature within $\pm 0.001\,^{\circ}\mathrm{C}$. By employing multiplying or binary techniques, frequency-generating devices in the range of from less than 1 Hz to more than 600 MHz are available. In the temperature-compensated crystal oscillator (TCXO), stability over a wide range of temperatures is obtained by a compensating network that shifts the frequency of the crystal by an amount approximately equal and opposite to the shift of frequency caused by the temperature change. This network eliminates the need for an oven. TCXOs are available with temperature stabilities of ± 0.5 ppm over a temperature range of minus 40 to plus $70\,^{\circ}\mathrm{C}$.

CRYSTAL PHASES (α^{-}, β^{-}, γ^{-}, $\in^{-}$, η^{-}, etc.). Certain alloy systems may form different crystal structures, according to the relative proportions of the constituents, e.g., Cu-Zn, for which no less than five different phases are known. In many cases, the same crystal structure occurs with quite different constituent metals, so that it is often possible to use one expression such, for example, as β-phase, to cover a wide variety of compounds all having the same basic structure. This effect is explained by the Hume-Rother rules. Pure substances, as well as alloys, may exhibit more than one crystal structure, depending on temperature and past history, e.g., cobalt, iron, titanium.

CRYSTAL PICKUP. Since piezoelectric crystals produce electrical voltages when subjected to mechanical stresses they offer possibilities for various electromechanical processes. One of these is the phonograph pickup, where the phonograph needle operating in the groove of the record must transmit mechanical motion to something which will convert it into electrical effects so electronic amplifiers may be used. The crystal is one of the most sensitive and at the same time one of the highest fidelity devices for doing this. While many crystals exhibit the piezoelectric effect, Rochelle salt is the most sensitive and is used for pickups, microphones, etc. Among the other crystals used, quartz is noted for its durability. Through a mechanical linkage the motion of the needle is transmitted into mechanical stresses on the crystal and hence produces electrical effects which may be amplified and then converted to sound by the loudspeaker.

CRYSTEINE. See **Amino Acids**.

CUBE. 1. A solid bounded by six planes, having its face angles all right angles, and its twelve edges equal. 2. The third power of a number or quantity.

CUBIC EQUATION. An algebraic equation of the third degree in one or more variables but usually taken to mean the case of one variable so that its most general form is $a_0x^3 + a_1x^2 + a_2x + a_3 = 0$. Equations for its three roots have been known to mathematicians since the sixteenth century and many different forms of them can be given. All of them are relatively complicated, but the following procedure is probably as simple as any.

First substitute $x = y_1 - a_1/3a_0$ to get $a_0y^3 + b_2y + b_3 = 0$ and then convert this into $y^3 + py + q = 0$, where $p = b_2/a_0 = (3a_0a_2 - a_1^2)/3a_0^2$; $q = b_3/a_0 = (2a_1^3 27a_0^2a_3 - 9a_0a_1a_2)/27a_0^3$. Its three roots are $y_1 = u + v$; $y_2 = e(u + ev)$; $y_3 = e(eu + v)$, where e is either one of the complex cube roots of unity, $(-1 \pm i\sqrt{3})/2$. In order to calculate u and v let

$$D = \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}$$

then

$$u = \sqrt[3]{\frac{-q}{2} + D}$$

where any one of the three roots may be taken and

$$v = \sqrt[3]{\frac{-q}{2} + D}$$

but the relation $v = -p/3u$ must hold. The solution y_1 is known as Cardan's formula (1515).

The general solution can be somewhat simplified, depending on the nature of the roots.

1. $D^2 > 0$. One root is real, the two others are conjugate imaginary. If the real root of u is chosen, then v is also real and y_1 is the real root of the cubic.

2. $D^2 = 0$. In this case there are three real roots, two of which are equal, and the general equations become $y_1 = \sqrt[3]{-q/2}$, $y_2 = y_3 = -y_1/2$.

3. $D^2 < 0$. All roots are real and none are equal. From the definition of D, p, < 0 or $p = -P$, where P is a positive quantity. A trigonometric substitution is now convenient.

$$\cos\phi = \frac{-3\sqrt{3q}}{2P\sqrt{P}}$$

where ϕ can be taken in the first quadrant by proper choice of the sign of $\sqrt{P/3}$. The roots are then

$$y_k = \sqrt[2]{\frac{P}{3}} \cos\frac{1}{3}(\phi + 2k\pi), k = 0, 1, 2$$

These are the three real roots of $y^3 - Py + q = 0$.

Although straightforward in principle, application of these formulas is quite cumbersome and they are seldom useful in any practical case. Certain equations, combined with graphs and numerical tables, which give approximate roots for the cubic may be found in the literature, but these are also rather complicated. Unless there is some particular reason for doing otherwise, one should select a computer aided numerical method (see also **Approximate Calculation**) if one needs to solve a cubic equation.

CUCKOO CLOCK. See **Clocks**.

CUCKOOS AND COUCALS *(Aves, Cuculiformes, Cuculidae).* This family of birds is widespread, and many species can be found in all continents except Antarctica. Their length is from 14–70 centimeters ($5\frac{1}{2}$–$27\frac{1}{2}$ inches) and the weight is 25–1000 grams (0.8–35 ounces). The bill curves downward slightly with a protruding hook at the tip of the upper mandible and a deep cleft to the beak. The birds have 13 to 14 cervical vertebrae. The lateral toe is reversed. The main food is insects. Cuckoos and coucals have very different habitats. Most species are unsociable. Of the 128 species, 50 are brood parasites, and the clutch of the remaining species numbers from 2–6 unmarked eggs. In contrast, the eggs of many brood parasites are spotted. Eggs are laid at 2-day intervals, and at intervals of 1 day only in the smallest species. Incubation in the nonparasitic species begins after the first egg is deposited. The young, as they hatch, are rosy-red or dark red and blackish, naked or only very sparsely covered.

Cuckoos and coucals have 7 subfamilies: 1. Cuckoos (*Cuculinae*); 2. *Coccyzinae*; 3. *Phaenicophaeinae*; 4. *Crotophaginae*; 5. Ground Cuckoos (*Geococcyginae*); 6. *Couinae*; 7. Coucals (*Centropodinae*).

Cuckoos usually have inconspicuous colors, such as light gray or light brown to deep red-brown and black. The plumage of many is shiny or shimmering. The basic color is often overshadowed by light or dark transverse bands and less often by longitudinal striping, particularly below, on the wings and the tail. Aside from the large yellow and green areas of the Didric cuckoo, the only vivid colors in cuckoos are the frequently colored bills, the red eyes (mostly in older birds), and the colored or sometimes black, naked areas about the eyes.

The Coucal (*Centropodinae*) reaches a length of 36–70 centimeters (14–$27\frac{1}{2}$ inches). The skin is thick and dark; the innermost back talon is almost straight and usually elongated (in other cuckoos it is more curved and short). The wings are short and the legs are long; the bill is powerful. The colors are distributed over large areas, usually black, red-brown ranging to light brown and white, sometimes with white shaft streaks. The birds have a masterful way of using their legs to crawl and climb through the densest grasses and the most tangled foliage and lianas. Their diet is varied: arthropods, such as grasshoppers, ants, centipedes, and scorpions, as well as snails, frogs, lizards, snakes, and small birds. The nests are usually globular and have a side entrance, but also are sometimes hidden under grass, or are bowl-shaped like those of crows. The clutch size is from 2 to 5; the eggs are white and covered with a thick, leather-like, chalky layer.

There is only 1 genus with 26 species; among them are: 1. The Violet Coucal (*Centropus violaceus*); 2. The Bismarck Coucal (*Centropus ateralbus*); 3. The Pheasant Coucal (*Centropus phasianinus*); 4. *Centropus goliath*; 5. The Common Coucal (*Centropus sinensis*); 6. *Centropus toulou*; 7. The Gabon Coucal (*Centropus anselli*); 8. The Senegal Coucal (*Centropus sensgalensis*); 9. The White-Browed Coucal (*Centropus superciliosus*); 10. *Centropus melanops*. See also **Cuculiformes**.

CUCKOO WASP *(Insecta, Hymenoptera).* Small wasps that lay their eggs in the nests of solitary wasps and bees. Usually metallic blue or green. Family *Chrysididae*.

CUCULIFORMES *(Aves).* Terrestrial birds that range in length from 14 to 70 cm (5.5 to 27.5 in) and in weight from 25 to 100 gm (0.8 to 3.5 oz). The tail is usually relatively long and has 10 rectrices (a quill in a bird's tail, especially a long feather of use in steering), and 8 in those birds which inhabit the warmer parts of America. The feet are grapplers with the lateral toe either permanently pointing back or reversed. The posterior edge of the sternum has 2 notches on each side; one of them may form a window or else be lacking. The young remain in the nest for a comparatively long time; many leave the nest before they are able to fly. Their area of distribution covers all continents except Antarctica. There are 2 families: 1. Turacos (*Musophagidae*), and 2. Cuckoos and Coucals (*Cuculidae*). There are 40 genera with 146 species.

Turacos differ markedly from cuckoos and coucals. Each family has its diagnostic characteristics and is easily distinguishable. The feathers are shed in such a way that the two neighboring feathers of each one lost persist (saltatory or transilient moulting). In all comparable birds, the wing moulting proceeds from one feather to the next, unless the moult is entirely irregular, or else the feathers are shed simultaneously. Repeatedly, the relationship between the turaco and the gallinaceous birds, particularly the megapodes, the pheasants, and the hoatzins, is emphasized. See also **Cuckoos and Coucals**; and **Turacos**.

CUCURBITACEAE. A small family of plants, largely restricted to tropical or warm climates. Most of its 650 species are climbing or trailing herbaceous plants, which grow very rapidly. They are mostly annuals. The stems are hollow and in most species abundantly supplied with stiff bristly hairs. The large leaves are borne alternately on the stem, have a distinct, often long, petiole, and show a variety of shapes. The tendrils, which are a conspicuous feature of many members of this family, appear in the axils of the leaves and are interpreted as stems modified greatly. They are very sensitive organs, responding to the lightest touch of any solid substance, and often show a change in the direction of twining in the middle of a single tendril. In many species the nutating or circling movement of the tendril is very rapid. The flowers are axillary, either borne singly or in various types of inflorescence, and are usually yellow or white. The plants are either monoecious or dioecious. The calyx is adnate to the inferior ovary, the corolla is 5-lobed and inserted on the calyx. The stamens are typically five, but show great variation in number through fusions. The inferior ovary is 1- to 3-celled and usually contains many flattened seeds. The latter lack endosperm. The fruit is a variety of berry called a pepo, differing from a berry in that the receptacle enters into the formation of the rind or outer wall. The germination of the seeds of the commonly grown members of this family exhibits one rather striking peculiarity. When the arched hypocotyl emerges from the seedcoats a small peg forms on its lower end. This peg prevents the seedcoats from sticking to the cotyledons, which are withdrawn and carried into the air by the straightening of the arched hypocotyl. Many members of this family are grown in cultivation, as for example squashes, pumpkins, and cucumbers, and certain ornamental species, like *Echinocystis*, *Momordica*, and some of the gourds.

Cucurbita, pumpkins and squashes. These are rather coarse annual vines having very rough bristly stems, large, long-stalked leaves and axillary (axil) flowers of two kinds. The staminate (stamen) flowers have long stalks while the pistillate flower stalks, or peduncles, are short. Staminate flowers have a rudimentary ovary while pistillate flowers have three staminodia, or vestigial stamens; in both kinds of flowers the 5-lobed yellow corolla is conspicuous. Insect-pollination is usual. It is probable that these plants are native to tropical America, where they have been long cultivated. Cultivation is now widespread.

Pumpkins, *Cucurbita pepo*, are of many varieties, sizes and shapes. Included here are the Field Pumpkin, Sugar Pumpkin, Pie Pumpkin and Mammoth Pumpkin, Fordhook, Scallop (Petty-pans), Crookneck Squashes, and Marrow Squashes. In this group the stems are prickly as a rule, and more or less 5-angled.

Squashes, *Cucurbita maxima*, are plants having cylindrical stems which are hairy rather than bristly. Here are found Hubbard squashes, turban squashes and mammoth squashes, the latter often of immense size and frequent occurrence, sometimes weighing over 100 pounds. *Cucurbita moschata* includes cushaw and cheese types of squashes.

Cucumis, Muskmelons, Cantaloupes and Cucumbers. The plants in this genus are considered to be natives of tropical Asia and Africa and the East Indian Islands, where they have been in cultivation for many centuries. In these plants the tendrils are unbranched, the staminate flowers are borne in small clusters in the axils of the leaves, while the pistillate flowers are solitary. Many more staminate flowers are formed than pistillate, to insure successful pollination, which is almost entirely by insects.

Cucumis melo includes melons of various kinds, among them muskmelons and cantaloupes. Many varieties bear inedible fruits, some of which may be used in making preserves. Few of these are cultivated in American gardens. The fruits have a warted or ribbed skin, but never hairy or spiny. They are probably native to southern Asia.

Cucumis sativus is the cucumber. This is a native of the East Indies. There, and in Asia, cucumbers have been cultivated since earliest times. Many varieties have been developed. Certain varieties, grown under glass, are often seedless. Others are largely grown for pickling. The best pickling fruits are grown in regions having a cool climate. For pickling, the fruits are picked while still young and small. They are first salted in brine, after which they are bottled in vinegar, often with the addition of various spices or other flavorings, such as dill, or mustard, or peppers.

Gherkins, *Cucumis Anguria*, are native to the West Indies. Small cucumbers are also frequently called gherkins.

Citrullus. Watermelons, Citron and Colocynth. These are natives of Asia, Africa and southern Europe. They are coarse trailing vines with branched tendrils and lobed leaves.

Citrullus vulgaris includes the watermelon and citron as varieties. It is native to Africa, where it has been cultivated since the time of Egyptian supremacy. Watermelons are grown for the juicy tender flesh. In contrast to them, the flesh of the citron is firm and inedible when raw. It is grown largely for preserving or for pickling. Preserved citron is used in cakes and in the making of certain kinds of bread. Because the juice of the citron is rich in pectin, it is much used in making jellies, especially with fruits naturally lacking in pectin and hence not capable of "jelling."

Many members of this family are grown as ornamentals or for their curious and sometimes useful fruits. Many such are classed as gourds. One of these, *Lagenaria vulgaris*, a native of the Old World tropics, is known as the calabash gourd or bottle gourd, from the shape of its fruit. Excellent flasks are made from the woody pericarp.

Luffa cylindrica, the "bath sponge," is frequently seen in gardens. The vascular tissues of the pericarp form an intricate net that is sometimes used as a sponge. Many species of *Luffa* have edible fruits. Mostly they are natives of the Old World. Another gourd, a native of tropical America, is *Sechium edule*, grown for its edible fruit. Many other species of gourds have curiously ornamental fruits.

Ecballium elaterium, the squirting cucumber, found in Mediterranean regions, has a fruit which when mature is very turgid. When the fruit is broken, the seeds are forcefully ejected by the contraction of the pericarp. From the fruit is obtained a powerful purgative. See Fig. 1.

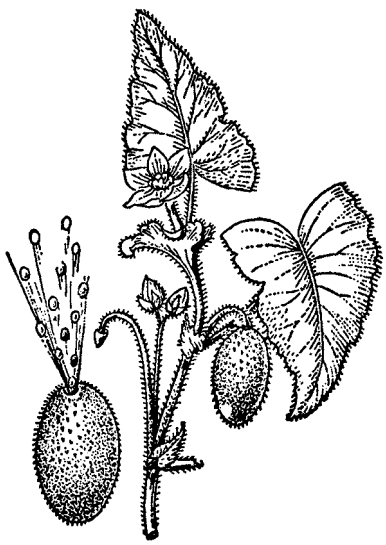

Fig. 1. Squirting cucumber. Pressure develops inside the fruit and, as it is detached, a hole is torn through which the seeds are violently discharged with the juice.

Citrullus colocynthis is another Cucurbitaceous plant, the fruit of which yields a drug. In this species pulp of the fruit gives colocynth.

Echinocystis lobata, a native American plant, is frequently grown for ornament, and as a vine to cover unsightly places quickly. Its small white flowers are pleasantly fragrant. The staminate flowers are borne in long-stalked many-flowered inflorescences, while the pistillate are borne singly and are very short-stalked. The tendrils of this plant are especially sensitive to touch and move very rapidly.

CUMIN SEED. See **Spices**.

CUMLIFORM. See **Clouds and Cloud Formation**.

CUMMINGTONITE. The mineral cummingtonite is a variety of amphibole which is essentially $(Mg, Fe, Mn)Si_8O_{22}(OH)_2$, the amounts of magnesium and iron varying as they replace one another. Cummingtonite is generally restricted to material containing from 50 to 70% $MgSiO_3$. The name *grunerite* has been applied to cummingtonite which contains more than 50% $FeSiO_3$. Cummingtonite usually occurs as a dark green to brown fibrous to lamellar mineral. It derives its name from Cummington, Massachusetts. See also **Amphibole**.

CUMULANTS. The cumulants κ_1, $\kappa_2 \ldots$ of a probability distribution function are defined by the identity

$$\exp\left[it\kappa_1 + \frac{(it)^2}{2!}\kappa_2 + \frac{(it)^3}{3!}\kappa_3 + \cdots\right] \equiv \left[1 + it\mu_1' + \frac{(it)^2}{2!}\mu_2' + \frac{(it)^3}{3!}\mu_3' + \cdots\right] \equiv \phi(it)$$

where μ_1', $\mu_2' \ldots$ are the moments of the distribution about the origin and $\phi(t)$ is the characteristic function. $\psi(t) = \log\phi(t)$ is called the cumulant generating function. κ_1 is equal to the mean μ_1' and the other cumulants can be expressed in terms of the moments about the mean; the first four can be given by $\kappa_1 = \mu_1'$, $\kappa_2 = \mu_2$, $\kappa_3 = \mu_3$, $\kappa_4 = \mu_4 - 3\mu_2^2$.

The cumulants other than the first are invariant under a change of origin. For the normal distribution all cumulants after the second are equal to 0; for the Poisson distribution all the cumulants are equal to μ. $\gamma_1 = \kappa_3/\kappa_2^{3/2}$ and $\gamma_2 = \kappa_4/\kappa_2^2$ provide measures of skewness and kurtosis.

CUMULATIVE EXCITATION. An excited atom, in the metastable state, may receive a further increment of energy by collision, as with an electron, and thus be raised to a still higher energy state. This process by which an atom is raised by collision from one excited state to higher states is known as cumulative excitation. In fact, it is possible for an atom in the metastable state to receive sufficient energy by this process to be ionized and this process is designated as cumulative ionization.

CUMULOSE. The term proposed by Merril in 1897 for sediments composed almost, if not entirely, of carbonaceous material, such as peat and lake mucks.

CUPOLA STRUCTURE (geology). In geology, cupola is the term proposed by R.A. Daly in 1911 for a subsidiary dome-like protrusion in the roof of a batholith. Cupolas are supposed to be the reservoirs for the concentrated rising gases for the batholithic magma and may serve as the loci for volcanoes.

CUPRITE. The mineral cuprite, cuprous oxide, Cu_2O, occurs as isometric crystals, usually octahedrons, but may be cubes, dodecahedrons or modified combinations. It also is found as a massive, earthy material. Its fracture is conchoidal to uneven; brittle; hardness, 3.5–4; specific gravity, 6.14; luster, submetallic to earthy; color, red; nearly transparent to nearly opaque. Its streak is shining brownish-red. Cuprite is a secondary mineral resulting doubtless from the oxidation of copper sulfides. It is often found associated with native copper, malachite and azurite.

Cuprite is a fairly common mineral, and of the many localities in which it occurs may be mentioned the Province of Perm, in the former U.S.S.R.; Chessy, France; Broken Hill, New South Wales; Corocoro, Bolivia; Andacollo, Chile; Bisbee, Arizona; and Del Norte County, California. Magnificent large transparent red gem crystals, some with a coating of malachite, have been found at Ojunga, S.W. Africa. The name cuprite is derived from the Latin *cuprum*, copper.

CURASSOW *(Aves, Galliformes).* Birds of a few species found in northern South America. They are about the size of turkeys and are arboreal in habit. Excellent as food and sometimes domesticated.

The guan of central and South America is related to the curassows. One species, the chachalaca, *Ortalis vetula*, enters southern Texas. See also **Galliformes**.

CURCULIO *(Insecta, Coleoptera).* The curculios are weevils which damage apple, apricot, cherry, grape, peach, pear, plum, quince, and various other stone fruits. See Fig. 1. The best known of the curculios is the *plum curculio* (*Conotrachelus nenuphar*), which damages plums, but also has allied specialists for apple, grape, and quince. The adult plum curculio is a small grayish-brown snout beetle, with black and white markings and four prominent dark humps on its back. The larva is a whitish mass, legless, slightly curved, with a brown head and reaching up to $\frac{3}{8}$-inch (9 to 10 millimeters) in length. Both forms of the insect are damaging. The adult feeds on fruit in spring, making crescent-shaped cuts in the fruit in which to lay eggs. The larva makes tunnels in the fruit as it eats its way through its food source. Distribution of the plum curculio is essentially east of the Rocky Mountains in the United States.

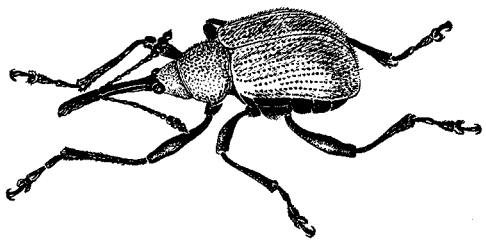

Fig. 1. Rose curculio. (*USDA diagram.*)

Fruit damaged by plum curculio usually falls before it is mature. Apples, for example, drop during May and June. It is highly advantageous to pick up prematurely fallen fruit and destroy it by burning, thus preventing any reinfestation. It is also well to cultivate the soil around all fruit trees affected by this pest during late spring and early summer to destroy the larvae and pupae in their cells in the earth. The adult curculio hibernates under leaves or trash in winter. All trash under which the beetle may find shelter must be destroyed. Overgrown hedges and fences are favorite hiding places for the insect.

Plum curculios are shy and prefer the deep shade when they do their damage. Therefore, trees should be properly pruned to admit the sun. Fertilizers should be used generously but judiciously to otherwise maintain healthy trees.

Natural enemies of the curculio include birds and parasites. Minute wasps (*Trichogramma*) attack the larvae in the fruit; other parasites attack the eggs. Both the adult curculio and larvae are attacked by fungal diseases. Lack of resistance to long and cold winters is also a factor.

Specialist species of the curculio, the habits and damage of which parallel those of the plum curculio, include:

Apple curculio (Anthonomus quadrigibbus). This is a grub, white soft, about $\frac{1}{2}$-inch (12 millimeters) in length. Also affects apricot.

Grape curculio (Craponius inaequalis). Larva is small, white, and features a brown head. In June and July, the insect infests the grape. The point of entry causes a small black hole in the skin, around which the fruit becomes discolored. The adult grape curculio is a grayish-brown, snout-type beetle, attaining a length of about $\frac{1}{10}$ inch (2.5 millimeters).

Quince curculio (Contrachelus crataegi). This insect is a bit larger than the plum curculio and has a different life-cycle. In the fall, the grubs exit the fruits and enter the ground, whereupon they hibernate and transform to adults, emerging during the late spring or early summer.

Rhubarb curculio (Lixus concavus). This insect is an elongated grub, attaining a length of about $\frac{3}{4}$ inch (18 millimeters), which bores into the crowns and roots of the rhubarb plant.

Walnut curculio. The adult is a beetle, about $\frac{1}{4}$-inch (6 millimeters) long, with a curved snout, and prominent humps and ridges on the wing covers. The larva is a white, legless worm with a brown head and ranging up to $\frac{1}{2}$ inch (12 millimeters) in length. The walnut curculio resembles the pecan weevil. The adult feeds on newly formed nuts and new foliage. Females lay eggs in nuts, causing them to drop prematurely. Distribution is throughout the United States.

CURETTAGE. Scraping of an organ, bony cavity, or other portion of the body with a curette or other instrument.

CURIE, PIERRE (1859–1906) CURIE, MARIE (1867–1934). Pierre Currie was born and raised in Paris. With his brother, Jacques, he studied crystals and in 1880 discovered piezoelectricity. Piezoelectricity is the production of an electric charge by pressure on certain crystals. Pierre became director at the School of Industrial Physics and Chemistry in Paris where he worked for 22 years. His doctoral thesis on magnetism led to his discovery, the Curie point, a temperature at which ferromagnetic substances lose their magnetism.

Pierre met a Polish born woman named Marie Sklodovska when she was studying mathematics, chemistry, and physics at the Sorbonne. They

married in July 1895 and began working together. In 1897, Marie began searching for a topic for her doctoral research. She became interested in Becquerel's work and decided to investigate the rays Becquerel had discovered coming from uranium. She discovered "radioactivity" from this work. Upon further research, Marie realized that the radiation coming from uranium ore was too large to be produced by uranium alone. Pierre stopped his research and began working with Marie on radioactivity in pitchblende. As a result, they discovered polonium and radium. It took the Curies years to obtain a few grains of pure radium. Their work revolutionized the scientific world's understanding of atomic structure. The Curies also introduced the technique of radiation therapy into medicine. In 1903, the Curies and Henri Becquerel shared the physics Nobel Prize for their work on radioactivity. Marie Curie was the first female recipient of a Nobel Prize.

In 1906, Pierre was killed. Marie continued her work, was the first woman to teach at the Sorbonne, and in 1911 won an unprecedented second Nobel Prize in chemistry for her discovery and study of polonium and radium. On July 4, 1934, Marie died of leukemia from exposure to radiation.

Marie's daughter, Irene, joined in the work at the Radium Institute. With her husband, Frederic Joliot, and under the combined name Joliot-Curie, continued the work of the Curies in 1935, the pair won a Nobel Prize for their discovery of artificial radioactivity.

See also **Curie-Weiss Law**; and **Radioactivity**.

J. M. I.

CURIE POINT (or Curie Temperature). Ferromagnetic materials lose their permanent or spontaneous magnetization above a critical temperature (different for different substances). This critical temperature is called the Curie point. Similarly, ferroelectric materials lose their spontaneous polarization above a critical temperature. For some such materials, this temperature is called the "upper Curie point," for there is also a "lower Curie point," below which the ferroelectric property disappears. See also **Ferromagnetism**.

CURIE-WEISS LAW. The transition from ferromagnetic to paramagnetic properties, which occurs in iron and other ferromagnetic substances at the Curie point, is accompanied by a change in the relationship of the magnetic susceptibility to the temperature. P. Curie stated in 1895 that above this point the susceptibility varies inversely as the absolute temperature. But this was found to be not generally true, and was modified in 1907 by P. Weiss to state that the susceptibility of a paramagnetic substance above the Curie point varies inversely as the excess of the temperature above that point. At or below the Curie point, the Curie-Weiss law does not hold.

CURIUM. [CAS: 7440-51-9] Chemical element, symbol Cm, at. no. 96, at. wt. 247 (mass number of the most stable isotope), radioactive metal of the Actinide series, also one of the Transuranium elements, mp estimated $1350 \pm 50\,^{\circ}\mathrm{C}$. ^{247}Cm has a half-life of 1.64×10^7 years. Other long-lived isotopes are ^{245}Cm ($t_{1/2} = 9320$ years), ^{246}Cm ($t_{1/2} = 5480$ years), ^{248}Cm ($t_{1/2} = 4.7 \times 10^5$ years), and ^{250}Cm ($t_{1/2} = 2 \times 10^4$ years). Other known isotopes are ^{238}Cm, ^{242}Cm, ^{244}Cm, and ^{249}Cm. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^7 6s^2 6p^6 6d^1 7s^2.$$

Ionic radius: Cm^{3+} 0.98 Å. See also **Chemical Elements**.

First identified in 1944 by G.T. Seaborg, R.A. James, and A. Ghiorso, who found ^{242}Cm in the product obtained by bombarding ^{239}Pu with alpha particles of resonance energies. Later L.B. Werner and I. Perlman produced and isolated the same isotope by the action of neutrons upon ^{241}Am.

In experiments the concentration of curium must be kept low in order to avoid the formation of a reducing medium due to the action of the ^{242}Cm alpha particles on H_2O. At a concentration of 10^{-5} molar in curium, and under conditions where americium(III) is oxidized to americium(VI) in the same solution, the curium is not oxidized above the (III) state with ammonium peroxydisulfate.

The solubility properties of curium(III) compounds are in every way similar to those of the other tripositive Actinide elements and the tripositive Lanthanide elements. Thus the fluoride and oxalate are insoluble in acid solution, while the nitrate, halides, sulfate, perchlorate, and sulfide are all soluble.

Solid curium trifluoride has been prepared by drying the fluoride, which precipitates from dilute HNO_3 upon the addition of hydrofluoric acid. Curium trifluoride can be reduced to the metal by heating at $1275\,^{\circ}\mathrm{C}$ in a beryllia crucible with barium vapor. The metal is silvery in color and has the properties of an electropositive element in common with the other Actinide elements.

The ion Cm^{3+} is colorless, as are its compounds generally. CmF_3 is hexagonal, Cm_2O_3 is white and CmO_2 is black and hexagonal. $CmCl_3$ is light yellow and hexagonal. Cm^{4+} is known in solution only as the complex fluoride.

In research at the Institute of Radiochemistry, Karlsruhe, West Germany during the early 1970s, investigators prepared alloys of curium with iridium, palladium, platinum, and rhodium. These alloys were prepared by hydrogen reduction of the curium oxide or fluoride in the presence of finely divided noble metals. The reaction is called a *coupled reaction* because the reduction of the metal oxide can be done in the presence of noble metals. The hydrogen must be extremely pure, with an oxygen content of less than 10^{-25} torr.

Curium was first isolated in the form of a pure compound, the hydroxide, of curium-242 (produced by the neutron irradiation of americium-241) by Werner and Perlman at the University of California in the autumn of 1947. Much of the earlier work with curium used the isotopes ^{242}Cm and ^{244}Cm, but the heavier isotopes offer greater advantages mainly because of their longer half-lives. The isotope ^{248}Cm, obtainable in relatively high isotopic purity as the alpha particle decay daughter of ^{252}Cf, is the most practical for chemical studies. See also **Radioactivity**.

A gram of ^{242}Cm generates approximately three thermal watts of energy-very high as compared with one-half thermal watt per gram of ^{238}Pu. This property has given consideration to the possible use of curium as an isotope power source.

CURL. A vector resulting from the action of the operator del on a vector, **V**. It can be written in Cartesian coordinates in the following forms:

$$\begin{aligned}\operatorname{curl} \mathbf{V} = \nabla \times \mathbf{V} &= \mathbf{i}\left\{\frac{\partial V_z}{\partial y} - \frac{\partial V_y}{\partial z}\right\} \\ &\quad + \mathbf{j}\left\{\frac{\partial V_x}{\partial z} - \frac{\partial V_z}{\partial x}\right\} + \mathbf{k}\left\{\frac{\partial V_y}{\partial x} - \frac{\partial V_x}{\partial y}\right\} \\ &= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \partial/\partial x & \partial/\partial y & \partial/\partial z \\ V_x & V_y & V_z \end{vmatrix}\end{aligned}$$

The curl of a position vector vanishes; $\mathbf{R} = \mathbf{i}x + \mathbf{j}y + \mathbf{k}z$, $\nabla \times \mathbf{R} = 0$. If the curl of a vector function vanishes everywhere in a certain region, the function is said to be an irrotational vector (or a lamellar vector), in this region. It follows that if **V** is an irrotational vector so that $\nabla \times \mathbf{V} = 0$, then $\mathbf{V} = \nabla\phi$ (**V** is the gradient of ϕ), where ϕ is some scalar function.

European writers often use the word rotation instead of curl and the symbol rot **V**.

CURL, ROBERT F., JR. (1933–). An American who won the Nobel Prize for chemistry along with Harold W. Kroto and Richard E. Smalley in 1996, the 100th anniversary of Alfred Nobel's death. The trio won for the discovery of the C_{60} compound called buckminsterfullerene. He graduated from Rice University and received a Ph.D. from the University of California, Berkeley in 1957.

See also **Buckminsterfullerene (Buckyballs)**; and **Carbon**.

CURRENT AMPLIFICATION. 1. Of an amplifier, the ratio of the current produced in the output circuit as a result of the current supplied in the input circuit, to the current supplied to the input circuit. 2. Of a magnetic amplifier control-winding, the ratio of the change in output current to the change in current in the control winding required to produce the output current change. Assuming the change from minimum to maximum output current to be 100%, the nominal current amplification is to be measured over the following range: An output current 20% greater than the minimum to an output current 20% less than the maximum. Current amplification is usually stated for operations of the magnetic amplifier at its rating except for control currents and output currents. The current amplification taken is the minimum that exists for any condition within the rating. 3. Of a multiplier phototube, the ratio of the output current to the photocathode current due to photoelectric emission at constant electrode voltages. Terms output current and photocathode current as here used do not include dark current. This characteristic should be measured at levels of operation that will not cause saturation. 4. Of a transducer, the ratio of the magnitude of the current in a specified load impedance connected to a transducer to the magnitude of the current in the input circuit of the transducer. If the input and/or output current consists of more than one component, such as multifrequency signal or noise, then the particular components used and their weighting are to be specified. By custom, this amplification is often expressed in decibels by multiplying its common logarithm by 20.

CURRENT ATTENUATION. Of a transducer, the ratio of the magnitude of the current in the input circuit of a transducer to the magnitude of the current in a specified load impedance connected to the transducer. If the input and/or output current consist of more than one component, such as multifrequency signal or noise, then the particular components used and their weighting need to be specified. By custom, this attenuation is often expressed in decibels by multiplying its common logarithm by 20.

CURRENT BALANCE. A system of fixed and movable coils of accurately known dimensions so arranged that the force developed between the coils (by the passage of electric current) can be balanced by the force of gravity acting on a known mass. Such an arrangement is used for the absolute determination of the ampere. See also **Electrical Instruments**.

CURRENT CORRECTION ANGLE (Navigation). The angle between the heading of a ship and the course of the ship relative to the earth. In sea navigation, the actual motion of the water relative to the surface of the earth is known as current. The direction in which the water is moving is known as the set, and the speed of motion is called the drift. Three main types of currents are recognized by navigators: general ocean currents, tidal currents, and currents due to wind. General ocean currents are discussed in publications of the United States and other governments, and are plotted on their monthly pilot charts. Likewise, tidal currents are predicted for any particular locality at any time. Currents due to winds are very difficult to determine with any exactness. Experience has shown that a wind that has been blowing steadily for several hours, will produce, in the northern hemisphere, a surface current that sets about 40° to the left. The drift of wind currents is between 1 and 3% of the speed of the wind producing it. Many variables, such as gustiness, steadiness of direction, etc., enter into the determination of wind currents, and only long experience will give anything approaching accurate set and drift. In the article on Dead Reckoning is discussed a so-called "current" that is the "catch-all" for various errors in dead-reckoning navigation.

If a ship is to make good a specified course in a region where a current is known to exist, the so-called current correction angle should be determined to find the proper heading for the ship. The determination of this angle may be made either by graphical or computational methods. Either method is sufficiently accurate, and the graphical method is more commonly used. However, the computational method is fully as rapid as the graphical, and does not require the space and paraphernalia needed for constructing the vector triangle. The graphical method is practically identical with that discussed under **Wind Correction Angle (Navigation)**.

The simplicity of the computational method is indicated in the following case: A ship is operating with cruising speed of 15 knots, in a region where a current is known to set 160° with drift of 3 knots. The navigating officer wishes to determine the proper heading for the ship in order that its actual motion relative to the surface of the earth shall be 270° (due west), and he also wishes to know the speed the ship will make good along this course. A freehand sketch is helpful, but by no means necessary. Such a sketch is shown in Fig. 1. The angle *xec* is known, since the current sets 160° and the course is to be 270°. The side cs is known, since the speed of the ship is 15 knots. Then, by means of traverse tables, slide rule, or any form of three-place computing, we have:

$$70^\circ \quad ec = 3.00 \text{ k} \quad ex = 1.03 \text{ k} \quad xc = 2.82 \text{ k}$$

$$esc = 11^\circ \quad cs = 15.00 \text{ k} \quad xs = 14.74 \text{ k} \quad xc = 2.82 \text{ k}$$

$$ex = 13.7 \text{ k}$$

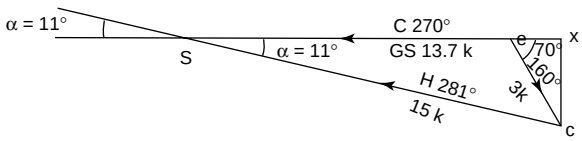

Fig. 1. Determination of current correction angle.

Hence, we have the heading to be used, given by 270° + 11° = 281°, and the predicted speed along the course of 13.7 knots. This work was done in about 2 minutes, using nothing other than a pencil, pad of paper, and the traverse tables.

Any one of the dead-reckoning computers, designed for air navigation, may be used for solving problems of this sort. When using these, care must be taken to remember that they are designed for use with wind, and that wind direction is given as opposite to that in which the air is actually moving; whereas the set of the current is properly given as the direction in which the water is moving.

See also **Course**; **Dead Reckoning**; and **Navigation**.

CURRENT DENSITY. 1. The limiting value of the time rate of flow of electric charge per unit area (perpendicular to direction of flow) as the area approaches zero. 2. In nuclear physics, a vector such that its component along the normal to a surface equals the net number of particles crossing that surface per unit area and unit time. Commonly referred to simply as current, as in neutron current. 3. By analogy with electric current, a vector representing the time rate of flow of any quantity such as mass or momentum, per unit area in a transport process.

CURRENT (OCEAN). See **Ocean Currents**.

CURRY POWDER. See **Spices**.

CURVATURE. A measure of the rate of change of direction of a curve. If τ is the angle made with the *OX*-axis by a point P on the curve and s is the arc length from some fixed point on the curve to P, the curvature at P is $\kappa = d\tau/ds$.

The radius of curvature is $\rho = 1/\kappa$. When the equation of the curve is given in one of the equivalent forms: (a) $y = f(x)$; (b) $x = f_1(t)$, $y = f_2(t)$, the parametric form; (c) $F(x, y) = 0$, the corresponding equations for the radius of curvature are: (a) $(1 + y'^2)^{3/2}/y''$; (b) $s_t^{2/}[x_{tt}^2 + y_{tt}^2 - s_{tt}^2]^{1/2}$; (c) $[(F_x^2 + F_y^2)^{3/2}]/(F_{xx}F_y^2 - 2F_{xy}F_xF_y + F_{yy}F_x^2)$. Equations can also be derived when the curve is described in polar coordinates.

Since any three points determine a circle, choose three arbitrary points P_0, P_1, P_2 on a plane curve and let P_1, P_2 approach P_0 along the curve to obtain a limiting circle for the curve. It is called the circle of curvature at P_0 or the osculating circle. Its center is the center of curvature and its coordinates are $X = x - \rho \sin\phi; Y = y + \rho \cos\phi$, where $\tan\phi = y'$.

See also **Circular Curves**.

CURVATURE OF FIELD (Optics). One of the five geometrical aberrations of lenses. If a system is corrected so that there is no spherical aberration, no coma, and no astigmatism, the images of off-axis points will lie on a curved surface called the Petzval surface.

CURVATURE OF LENS (Total). The quantity K, defined by the expression

$$K = \frac{1}{r_1} - \frac{1}{r_2}$$

is called the total curvature of a lens. Thus, for a thin lens:

$$\frac{1}{f} = (n-1)\left(\frac{1}{r_1} - \frac{1}{r_2}\right) = (n-1)K$$

CURVE. The locus of a point moving with one degree of freedom; that is, its path is defined with the aid of one parameter. In Euclidean space, this expression would be $x_1 = x_1(t), x_2 = x_2(t), \ldots, x_n = x_n(t)$, with $a \le t \le b$. If $x_1(a) = x_1(b), x_2(a) = x_2(b), \ldots, x_n(a) = x_n(b)$, the curve is *closed*. If, with this possible exception, distinct values of t produce distinct points, the curve is *simple*. If the total length of an inscribed polygonal line approaches a finite limit as the length of each side approaches zero, the curve is *rectifiable*. (See entries following.)

CURVE FITTING. It is often of interest to represent a set of experimental data by means of a mathematical equation, which can be used for interpolation or other purposes. If the theoretical relation between the experimental variables is known, the procedure is generally simple but in many cases a purely empirical equation must be assumed. Even where the theoretical equation is known, the latter type may be preferred because it is easier to use. (A typical example is the temperature variation of the heat capacity of a gas. The theoretical equation, exponential in form, is complicated; a polynomial with two or three terms is much more convenient.)

The problem considered here is the following: given a set of numbers $x_1, x_2, x_3 \ldots$ and $y_1, y_2, y_3 \ldots$ it is desired to represent these data by an equation $y = f(x)$. There are thus two parts to the problem (1) to choose an appropriate form for the equation; (2) to evaluate the constants in it.

The first step, usually a graphical one, is a plot of y against x. If a straight line results, the required equation is $y = mx + l$. If the plot is not a straight line, some change of variable may still give a straight line. Thus if the data fit the equation $y = ax^n$ a plot of $\log x$ vs. $\log y$ would be a straight line of slope n for $\log y = \log a + n \log x$. When no such transformation reduces the equation to linear form, a polynomial $Y = a + bx + cx^2 + dx^3 \ldots$, where $Y = y, y^2, \log y, x/y$, etc., should be tried. If the measured values of x are in arithmetic progression, as $x = 0, 0.1, 0.2, 0.3$, etc., and the nth differences of y are constant, a polynomial with last term of x^n will represent the data exactly. However, the labor involved in calculating the coefficients becomes quite great if n is larger than three or four.

Having chosen the appropriate equation, the constants in it must now be evaluated numerically. This can be done: (a) graphically; (b) by the methods of selected points, choosing as many (x_i, y_i) pairs as there are unknown constants and solving the resulting simultaneous equations for the constants; (c) by the method of averages, grouping all of the (x_i, y_i) pairs into a number of sets equal the number of unknowns, taking their averages, and again solving simultaneous equations; (d) by the method of least squares. Closeness of fit between observed and calculated points usually increases in going from method (a) to (d) but the work involved in computation increases in the same order.

CURVE (Higher Plane). Generally understood to mean one that is not a straight line or a conic section. Thus, if the equation describing the curve is algebraic, $F(x, y) = 0$, the polynomial is of degree greater than two. The curve could also be described by a transcendental equation.

Higher plane curves often receive some attention in elementary calculus courses, as they illustrate many of the principles studied there (see also **Singular Point of a Curve**). The examples discussed in this work include: Archimedes spiral, asteroid, brachistochrone, cardioid, Cartesian oval, catenary, cissoid of Diocles, conchoid of Nicomedes, Cornu spiral, cyclic curves, cycloid, epicycloid, evolute, folium of Descartes, hypocycloid, involute, lemniscate of Bernoulli, limaçon, lituus, logarithmic spiral, oval of Cassini, parabola (cubical and semicubical), parabolic spiral, quadratrix of Dinostratus, rose curve, sici spiral, spiral, strophoid, tractrix of Huygens, trisectrix of Maclaurin, trochoid, witch of Agnesi. The exponential, hyperbolic, logarithmic, and trigonometric functions could also be called higher plane curves.

CURVE (Plane). Analytically, a curve is defined by a function of two or more variables but the shape of the curve is described most readily by a graph of the function. Geometrically, a curve can be regarded as the locus of the equation that describes the motion of the generation point.

A curve in two dimensions is called plane; for three dimensions, see also **Curve (Space)**. In rectangular coordinates, a plane curve can be represented by the equations: (1) $F(x, y) = 0$; (2) $y = f(x)$; (3) $x = f_1(t), y = f_2(t)$. The third form is the parametric equation of the curve. If the parameter t is eliminated from the two equations in (3), the forms (1) or (2) result. If the locus of a curve is described by the end point of a line of variable length, its other extremity being fixed, polar coordinates are generally more convenient than Cartesian coordinates.

Plane curves may be classified in many different ways. Perhaps the simplest, but not the most important mathematically, is by the order, which is the degree of the defining equation in Cartesian coordinates. An algebraic curve of order one is thus a straight line; of order two, a conic section, or one of its degenerate cases, such as a circle. (For algebraic curves of order greater than two and transcendental curves see also **Curve (Higher Plane)**.)

Analytic geometry is mostly concerned with the simpler types of plane curves but the methods of calculus, differential geometry, and more advanced branches of mathematics are required for a complete study of curves. Plane geometry is the study of certain closed curves like the triangle, quadrilateral, polygon, and circle.

(For further properties of plane curves. See also **Asymptote**; **Curvature**; **Envelope (Mathematics)**; **Evolute**; **Length of a Curve**; and **Tangent (Geometry)**.)

CURVE (Space). If a curve does not lie in one plane, it is called skew, twisted, or a space curve. It could, for example, be regarded as formed by the intersection of two surfaces. Now, in Cartesian coordinates, a surface is described by an equation $F(x, y, z) = 0$, hence two simultaneous equations in three variables $F_1(x, y, z) = 0$, and $F_2(x, y, z) = 0$ will describe a space curve. If one variable, x for example, is regarded as independent, the other two could be expressed as $y = f_1(x), z = f_2(x)$. The first equation can then be interpreted as the projection of the space curve in the *XOY*-plane and the second equation as the projection of the space curve in the *ZOX*-plane. Projections on the *XOZ*-and *YOZ*-planes could be obtained in a similar way by elimination of y and x, respectively, from the pair of simultaneous equations $F_1 = 0$ and $F_2 = 0$. Finally, a space curve can be represented in terms of a parameter by three equations $x = \phi_1(t), y = \phi_2(t), z = \phi_3(t)$.

The differential properties of space curves lead to relatively complicated formulas in the usual notation of calculus but they are given compactly in vector form. Let $\mathbf{r}$ be a position vector for a point on the curve and, if s is arc length along the curve, $d\mathbf{r}/ds = \mathbf{t}$ is a unit vector, tangent to the curve. Then, if a prime means differentiation with respect to arc length $\mathbf{t}' = \mathbf{n}/\rho = \kappa\mathbf{n}$, where $\mathbf{n}$ is a unit vector in the direction of the principal normal to the curve, perpendicular to $\mathbf{t}$, and the scalar quantities are ρ, the radius of curvature, and κ, the curvature. Now define another unit vector by the equation $\mathbf{b}' = -\tau\mathbf{n}$, where the scalar τ is called the tortuosity of the curve and $\mathbf{b}$ is a unit vector in a direction called the binormal. The three unit vectors **t, n, b** constitute a righthanded system of mutually perpendicular vectors. The planes in which they lie are named respectively: (1) normal, $\mathbf{b}$ and $\mathbf{n}$; (2) osculating, $\mathbf{n}$ and $\mathbf{t}$; (3) rectifying, $\mathbf{t}$ and $\mathbf{b}$. The following relations are known as the Serret-Frent formulas: $\mathbf{t}' = \kappa\mathbf{n}; \mathbf{n}' = \tau\mathbf{b} - \kappa\mathbf{t}; \mathbf{b}' = -\tau\mathbf{n}$.

The arc length of a space curve is conveniently given in terms of the parametric equation. Between the points t_0 and t_1 the result is

$$s = \int_{t_0}^{t_1} \left\{\phi_1'(t)^2 + \phi_2'(t)^2 + \phi_3'(t)^2\right\}^{1/2} dt$$

See also **Surface**.

CURVILINEAR ORTHOGONAL COORDINATES. A curvilinear system of coordinates α, β, γ is generated by a system of three mutually orthogonal families of surfaces $\alpha =$ constant, $\beta =$ constant, $\gamma =$ constant. It is assumed that the unit tangent vectors **a, b, c** along the coordinate curves form everywhere a right-handed system, i.e., $\mathbf{a} \times \mathbf{b} = \mathbf{c}$.

An infinitesimal line vector $d\mathbf{l}$ is given by the expression

$$d\mathbf{l} = \mathbf{a}M\,d\alpha + \mathbf{b}N\,d\beta + \mathbf{c}P\,d\gamma$$

A volume element dV is given by

$$dV = M\,N\,P\,d\,d\alpha\,d\beta\,d\gamma$$

CUSHING, HARVEY WILLIAMS (1869–1939). Cushing was an American doctor who is remembered for being the greatest brain surgeon of his age because of his development of new techniques for brain surgery. Cushing came from a long line of doctors, his father, grandfather, and great-grandfather were all physicians so it seemed natural for him to enter the medical field. In 1895, Cushing received his M.D. from Harvard University.

Cushing studied brain surgery in London, then in 1896, returned to the United States and became part of the staff at The Johns Hopkins University Hospital. He worked hard and found funding for a new research laboratory and began working on animals to develop new techniques for human brain surgery.

Cushing's expertise became widely known in 1907 when he removed a meningioma tumor from General Wood who was the personal physician to Presidents Cleveland and President McKinley.

During WWI, Cushing went to Europe to help wounded soldiers. Interestingly, Cushing sometimes used a large electromagnet to remove shrapnel from the brains of soldiers instead of performing surgery.

Cushing is best known for Cushing's syndrome. This is a disorder common in women with a pituitary dysfunction due to a benign glandular tumor.

Especially in the medical world, Cushing is recognized for his biography of the famous physician, William Osler. This biography won him a Pulitzer Prize in 1926.

Cushing died on October 7, 1939 of a heart attack. Even today he is respected as one of America's greatest brain surgeons.

J. M. I.

CUSHING SYNDROME. See **Adrenal Disease**; **Adrenal Glands**; and **Pituitary Gland**.

CUSPATE FORELAND. A coastal headland of triangular shape, with its apex seaward and its sides concave. See also **Erosion (Geology)**.

CUSP (Mathematics). A singular point on a curve where there are two coincident tangents. If there is a branch of the curve on each side of the double tangent, the cusp is of the *first kind* (e.g., the semicubical parabola); if the two branches lie on the same side of the double tangent, the cusp is of the *second kind*. If the curve is represented by $f(x, y) = 0$, the condition for a cusp, and also for a point of osculation is

$$\left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 - \frac{\partial^2 f}{\partial x^2}\frac{\partial^2 f}{\partial y^2} = 0$$

CUSTARD WINDS. See **Winds and Air Movement**.

CUSUM CHART. An abbreviation for "cumulative sum chart." Such charts are used in quality control. When a series of values x_1, x_2, etc., occur in temporal order, as in the measurement of a variable on components coming off a production line, the cusum chart plots $\sum_{i=1}^{k} x_i$ against k and observes the departures from process control when they fall outside permissible sampling limits.

CUTANEOUS WARTS *(Verrucae)*. See **Papillomaviruses**.

CUTICLE. 1. For the use of this term in botany, **see also Leaf**. 2. In zoology, cuticle is the outermost layer of the integument. See also **Integumentary System**. As applied to the skin of the vertebrates this layer is composed of cells of ectodermal origin but in the invertebrates it indicates a noncellular layer secreted by the underlying cells. A cuticle of the latter type occurs in the parasitic flatworms, the rotifers, the roundworms and annelid worms, and the arthropods. The cuticle of insects is usually called the cuticula.

CUTICULA. 1. The thickened plate at the free end of some epithelial cells. 2. The layer of scales covering a hair. 3. The noncellular layer covering the bodies of some invertebrates. Some entomologists call the outer and inner layers of the chitinous cuticula of insects the epidermis and dermis. The terms epidermis, dermis, cuticle, and cuticula are loosely used.

CUTLASSFISHES *(Osteichthyes)*. Of the suborder *Trichiuridea*, family *Trichiuridae*, these fishes have an elongated, band-shaped body with a sharply tapering head. The fish is naked or covered with very tiny scales. The mouth opening is broad and has several large teeth on the jaws and palate. The dorsal fin originates just behind the head and runs the length of the body. A finlet may be present. There are 100 to 160 vertebrae. Cutlassfishes are divided into about 25 genera, most with very few species. They are known to have existed since the Lower Oligocene period, and teeth have been found in Eocene layers that resemble present-day *Trichirus* species.

Found in tropical and neighboring seas, cutlassfishes usually are in deeper parts of coastal waters, where they swim rapidly after schooling fishes. The cutlassfish (*Trichirus lepturus*) attains a length up to nearly 5 feet (1.5 meters) and is one of the most widely distributed species. It is encountered in tropical and subtropical parts of the Atlantic, and in the Indian and western Pacific oceans. In the Atlantic Ocean, it follows the warm currents to the coast of England, and occasionally penetrates the Mediterranean. The silver-white body terminates in a thin, almost hair-like tail shaft. Thus, these fishes are sometimes called *hairtails*. In some regions, such as on the Japanese coast (where it moves into shallow water in August and September), the species is extensively fished and regarded as quite flavorful. Usually in reporting total catches, the several species of cutlassfishes are not differentiated.

CUTOFF. 1. A particular point in a cycle, or magnitude of a quantity, at which a mechanism, electric circuit, or other system, cuts off some flow to or from it. Thus, the steam engine cutoff is that percentage of stroke accomplished by the piston, when the inlet valve closes and prevents more steam from entering the cycle from the boiler. The cutoff of a Diesel cycle is the fraction of the stroke accomplished when supply of fuel oil to the cylinder is stopped. 2. A technique used in theoretical physics when the theoretical contribution to the value of a physical quantity arising from integration over part of the range of a certain parameter is not to be believed, in particular when such a contribution is infinite. The integral is cut off, usually at some high frequency limit, with the acknowledgment that beyond this limit either the method of approximation, or the theory itself, will have to be modified in the future.

CUTOFF FREQUENCY. 1. Of a transducer, either a theoretical cutoff frequency or an effective cutoff frequency. The latter is the frequency at which the insertion loss of a transducer between specified terminating impedances exceeds, by some specified amount, the loss at some reference point in the transmission band. 2. Of a wave filter, the frequency at which the attenuation begins to increase sharply. In the ideal filter, the attenuation would go to infinity at the cutoff frequency, but in a practical filter, the rise in attenuation is not so abrupt, and never reaches infinity, but does usually go to a very high value. 3. For a given transmission mode in a nondissipative, uniconductor waveguide, the frequency below which the propagation constant is real.

CUT SET. In the theory of linear graphs the concept of a cut set is almost as important as that of a tree. A cut set of a connected graph G is a set of edges such that the deletion of these edges reduces the rank of G by one. Moreover, no proper subset of this set possesses this property.

Clearly, the removal of the cut set of edges must yield an unconnected graph since the number of vertices v is invariant and rank $G = v - 1$. Thus by "cutting" this set of edges the graph is separated into two pieces. One of the pieces can be an isolated vertex. This latter case occurs for example if all the edges incident at a vertex are removed. As a matter of fact, the totality of edges incident at a given vertex is a cut set if and only if the vertex is not a cut vertex. Another and deeper characterization of a cut set is as a minimal set of elements which contains at least one branch from every tree. Again, a single non-circuit element constitutes a cut set whereas a single circuit element does not.

See also **Graph (Mathematics)**; and **Tree (Mathematics)**.

CUT SET (Fundamental). Suppose G is a linear connected graph (see also **Graph (Mathematics)**) possessing v vertices and T is one of its

trees. Each cut set of G must contain at least one branch of T. Those $v-1$ cut sets of G that include exactly one branch of T are said to be fundamental with respect to T. The orientation of a fundamental cut set of a directed graph (see also **Digraph**) is usually chosen to agree with that of the defining branch.

CUT SET MATRIX. The cut set matrix $Q_a = (q_{ij})$ of a *directed graph* G is defined in the following manner:

a. Q_a a has one row for each cut set of the graph and one column for each edge
b. $q_{ij} = 1$ if edge j is in cut set i and the orientations agree (see also **Cut Set (Oriented)**)
c. $q_{ij} = -1$ if edge j is in cut set i and the orientations disagree
d. $q_{ij} = 0$ if edge j is not in cut set i

The rank of Q_a is $v-1$, v denoting the number of vertices in G.

The cut set matrix Q_a and vertex matrix A_a are rather intimately related. For example:

1. If G is nonseparable, Q_a contains A_a (with some rows possibly multiplied by -1) as a submatrix.
2. If Q is a cut set matrix of $v-1$ rows and rank $v-1$ of a connected directed graph G of v vertices and A is the vertex matrix of G,

$$Q = DA$$

where D is nonsingular.
3. Under the same restrictions as in 2, the nonsingular submatrices of Q of order $v-1$ are in one-to-one correspondence with the trees of G. That is to say, each such submatrix is the *fundamental cut set matrix* of some tree. Conversely, any fundamental cut set matrix appears as a submatrix of Q.

See also **Graph (Mathematics)**; and **Tree (Mathematics)**.

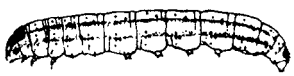
CUT SET (Oriented). Let G be a linear connected graph. The removal of a cut set of edges decomposes G into two connected pieces A and B. The cut set is oriented by ordering A and B either as (A, B) or (B, A). Each element of the cut set must have one vertex in A and one vertex in B. Suppose the cut set is oriented as (A, B). Then, an oriented element of the cut set is said to have the same orientation as the cut set if it is directed away from its vertex in A and toward its vertex in B.

See also **Graph (Mathematics)**.

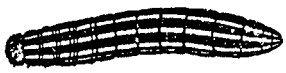
CUTTLEFISH *(Mollusca, Cephalopoda)*. Mollusks related to the squids but forming a separate family (*Sepiidae*). Used as food in the Oriental region. The shell is the cuttlebone of commerce and the ink sac secretes the pigment sepia. See also **Invertebrate Paleontology**.

CUTWORM *(Insecta, Lepidoptera)*. The cutworm is the larval form of any of numerous species of moth (usually owlet moths, *Noctuidae*). Or, a cutworm may be described as a caterpillar. Sizes range up to 2 inches (5 centimeters) in length. Most species feed at night and cut plants off at their base, cut leaves from stems, or chew holes in leaves. They most frequently are found curled up in the soil near a freshly damaged plant during the day. The wide variety of cutworms is evidenced by just a few that are illustrated in Fig. 1. Assumption of the daytime curled position of a representative cutworm is shown in Fig. 2. Cutworms are extremely damaging to crops and injurious to maize (corn) in particular. Infestations of cutworms may require replanting a stand of corn. In years past in some areas, an infestation may have destroyed from 5 to 50% of the corn crop. The army cutworm (not the true armyworm, which is described in another entry by that title) can be devastating to a corn crop. Other crops that can be severely affected by cutworms include bean, beet, cabbage, onion, and pea, although very few crops are immune to attack.

The corn cutworm (*Agrotis, Hadena,* etc.) is a soft-bodied caterpillar that feeds on young plants, cutting or segmenting the plant as it proceeds. Preventative measures for control of cutworms include early plowing of land intended for maize (corn) planting; turning pigs onto pasture land to be used later for planting; using a seed-drill to form a line of poisoned bran. Chemicals effective on cutworms include toxaphene, chlordane, and dylox (trichlorfon). The insecticide is applied to the soil surface before planting if cutworms are known to be present. Where damage to young plants is noticed, the chemical should be applied to the soil about the base of the plants. Baits should be applied in late afternoon.



Black cutworm



Bronzed cutworm

Fig. 1. Larvae of representative cutworms.

Glassy cutworm

Spotted cutworm

Fig. 2. Typical curled posture of cutworm resting on top of soil during daytime, usually near a freshly damaged plant.

Care should be taken to avoid contamination of edible parts of plants with the insecticide and none of the mentioned chemicals should be used on kale, spinach, turnip, or mustard. At least 21 days should be allowed on cabbage before harvest; and 28 days on collard after the last application of insecticide.

One useful classification of cutworms is: (1) *Solitary, surface cutworms* that feed on a plant just above or just below the soil level. The insect usually moves on to another plant once a sufficient amount of the plant has been consumed to cause it to topple over. This habit emphasizes the great damage that can be done in a very short time. Cutworms that fall into this classification include the black, the bronzed, the clay-backed, and the dingy cutworm. (2) *Climbing cutworms*, which in contrast with the surface cutworm, ascend the plant and attack the buds, leaves, and fruits of vegetable and orchard crops. In this category will be found the variegated and the spotted cutworms. (3) *Army cutworms*, which invade a planted area by the thousands. Practically all vegetation in any given area is consumed by this army of caterpillars, whereupon the insects proceed to a new, untouched field. The rate of damage by such infestations can be total within just a few days. (4) *Subterranean cutworms*, which remain in the soil and consume roots and all underground segments of plants. In this category will be found the pale western and the glassy cutworms.

With most common cutworms, there is only one generation per year. Although there are several variations in life cycle, typically the worms will winter over as small larvae in the soil or under plant residuals and debris. Their feeding commences in the spring and their growth is steady

until very late spring or early summer, depending upon locale and species. Then they change to a pupal stage, after which they are adults (moths). About 2 weeks or considerably less for some species are required for the egg stage. Growth from tiny caterpillars only a small fraction of an inch in length up to approximately 2 inches (5 centimeters) in length may require from 2 to 5 months, again depending upon species and locale. At this point the insects burrow into the soil, often to a depth of several inches, where they pupate for several weeks, or in some cases, overwinter. Then the new adults crawl from beneath the surface, aided by tunnels constructed by larvae making their way into the soil. A subclassification in terms of life cycle can be made: (1) *Single-generation species*, most frequently found in the more northern climes. This category of cutworm winters as larvae. It is interesting to note that the insect is confined to one generation per year because the prepupal stage is retarted by relatively high ground temperatures. (2) *Several-generation species*, most frequently found in southern climes. These insects winter over as pupae. Weather conditions greatly affect the numbers of all species of cutworm. Wetness, for example, delays the moths in laying eggs, sometimes preventing this altogether; or flooding of the soil may cause the larvae to surface from within the soil and thus exposing them to their natural enemies, notably parasites.

Some of the more destructive cutworms include the following:

Black cutworm (*Agrotis ypsilon*, Rottemburg). Life cycle varies with location, ranging from a couple of generations per year in the northern states and Canada to perhaps 3 or 4 generations in mid-southern states, such as Kentucky, Tennessee, and Arkansas. The larva ranges from gray to brown in color and has a pale light striping.

Dingy cutworm (*Feltia subgothica*, Haworth). Mainly found in northern climates, produce one generation per year, and winter over as partially grown larvae. The dingy cutworms are resistant to drought and tend to be climbers. Larva is dull brown, featuring a gray dorsal stripe.

Bronzed cutworm (*Nephelodes emmedonia*, Cramer). Essentially a northern species, this insect is injurious to maize (corn), grains, and grasses. There is only one generation per year and the insect winters as a partially developed larva. The larva is a dark bronze color and striped from head to tail by 5 pale brown lines.

Variegated cutworm (*Peridroma saucia*, Hubner or *margaritosa*, Haworth). This cutworm occurs throughout the United States and, in some years, has destroyed many millions of dollars in crops. Preference of the insect is for garden vegetables, vine and tree fruits, and glasshouse plants. From 3 to 4 generations per year are possible. The insect winters over mainly in the form of pupae. Some 60 eggs may be laid at a time, usually on stems and leaves of plants. The larva is of a noticeable yellow color and a W design appears on the eighth abdominal segment.

Spotted cutworm (*Amathes* or *C. nigrum*, Linne). A widely distributed insect throughout Europe, Asia, and North America. Garden vegetable crops are a favorite target of the insect. There are from 2 to 3 generations per year. The insect winters over as a large larva. Eggs are found in groups of about a hundred, mainly on leaves.

Army cutworm (*Chorizagrotis auxiliaris*, Grote). Widely distributed, but well adapted to arid conditions. This insect is a surface feeder and generally operates in very large numbers, as an army, as previously described. Records indicate that over 100,000 acres (40,470 hectares) of wheat were destroyed in Montana in one year by this pest. There is one generation and the insect winters over as a half-developed larva. The eggs are laid upon the soil. Larva is a pale gray-green or perhaps brown. There is a pale black stripe along the back. Although there are no prominent markings, there is a splotchy appearance made up of fine white and brown areas. The skin is granular in texture. See also entry on another species, **Army Worm**.

Pale western cutworm (*Agrotis orthogonia*, Morrison). This cutworm is another major destroyer of crops, notably alfalfa, beet, and small grains in the western United States and Canada. There is one generation per year. Larvae hatch during the winter and early spring, whenever temperatures are sufficiently warm to trigger the development. Their feeding and hence crop destruction is usually complete by early July. The body of the insect is gray with no particular markings. The skin is granular. Eggs are laid in the soil.

Glassy cutworm (*Crymodes, Sidemia devastator*, Brace). Distributed throughout the United States, but not common in the southern states. This insect lives in the soil and like other subterranean species is particularly difficult to diagnose early and to control. A small larva winters over and there is only one generation per year. Similar to a grubworm, the insect's body is a greenish white. The small, somewhat red-colored head has a glassy appearance, hence the name. There are no granulations in the skin.

Yellow-striped armyworm (*Prodenia ornithogalli*, Guenee). Also called the cotton cutworm, this insect occurs in several areas of the United Stated, but is common in the southern states. The insect feeds on a wide variety of crops. Young plants are a special favorite. The larva has a triangular black spot on most segments, coupled with a brilliant orange stripe.

Southern armyworm (*Prodenia eridania*, Cramer). This insect is very common in the southern United States and sometimes is a major pest on vegetable crops. There are four or more generations per year. It is interesting to note that the female moth covers her eggs with whitish hairs. The fully developed larva is gray-to-black and marked with yellow stripes.

CUVIER, GEORGES LÉOPOLD CHRÉTIEN FRÉDÉRIC DAGOBERT, BARON DE (1769–1832). Cuvier was a French zoologist, comparative anatomist, and administrator, well known for his "catastrophism," but also one of the principal founders of geology as a geohistorical science.

Cuvier came from a Huguenot bourgeois family in Montbéliard, later to become part of Württemberg in Germany. After study in Stuttgart, he gained employment as tutor to an aristocratic family in Normandy, where he studied the local natural history and "mineralogy" (geology) and was influenced by the ideas of the diluvialist earth scientist J-A Deluc. In 1795, Cuvier moved to Paris and obtained a junior post at the Muséum National d'Histoire Naturelle, but was soon lecturing there and was elected to the Institut National, successor to the old Académie, eventually becoming its permanent secretary. Cuvier was also promoted to a chair in comparative anatomy at the Muséum, obtained Napoleon's favor, and became Inspector General in the Department of Education. His distinguished scientific and administrative career was cut short by the cholera epidemic of 1832, but he had long been the most powerful scientist/bureaucrat in France.

With access to the Muséum's rich collections, Cuvier's early work was devoted to the study of different living types of elephants and their extinct relatives: mammoths and mastodons. He knew how the modern types were articulated, which enabled him to reconstruct the skeletons of the extinct species. Subsequently, working on similar principles, he reconstructed fossil vertebrates from the Paris region. He compared French fossils with living American and Australian opossums, predicted the occurrence of certain marsupial-characteristic bones in the French fossils, and then displayed them by dissection. This fortified his belief that comparative anatomy should be a rational science with predictive capacity. See also **Paleontology (The History)**.

With Alexandre Brongniart, Cuvier prepared a geological map of the Paris Basin (accompanying their *Essai sur la Géographie Minéralogique des Environs de Paris*, 1811), and began to work out its geological history, recognizing changing conditions (e.g. freshwater or marine) over time, as judged by the nature of the deposits. Thus his work was "geohistorical" and as such he was one of the principal founders of stratigraphy and hence modern geology. Further, Cuvier used the principle of "the present as the key to the past" ('Le premier pas á faire pour deviner le passé, c'étoit de bien constater le présent').

Nevertheless, Cuvier thought that conditions at the time of mammoths (say) were substantially different from those at present, and that the passage from past to present conditions had proceeded by some kind of catastrophe. Indeed, Cuvier believed that from time to time the "thread of nature" was broken and no forces acting today could account for the series of catastrophes that seemed to be evidenced by the strata and their fossil contents. Through the course of the supposed sequence of catastrophes, however, animal forms gradually became more like those alive today. So Cuvier was a progressionist, but he was strongly opposed to transformist doctrines of his colleague Jean-Baptiste Lamarck, which seemed to Cuvier to be contradicted by the stratigraphic evidence. He also controverted Étienne Geoffroy Saint-Hilaire's ideas, which envisaged continuities between living forms that could be demonstrated by dissection–continuities even between invertebrates and vertebrates. Cuvier 'won' that debate fairly unambiguously by empirical argument. See also **Lamarck, Jean-Baptiste Pierre Antoine de Monet de (1744–1829)**; **Mass Extinctions**; and **Paleoclimatology**.

It is unclear whether Cuvier believed that "catastrophes" were universal, or how he thought new species came into being. In his 'Preliminary Discourse' to his *Recherches sur les Ossemens Fossiles* (1812), he envisaged partial inundations (perhaps like "mega-tsunamis") that could have

destroyed the animals of some continents, which area might subsequently be restocked by migrations from unaffected areas. In other passages, however, he hinted at universal catastrophes. While regarding the earth as very ancient, he remained agnostic as to how species arose, and seemed not to contemplate gradual extinctions under gradually changing conditions.

Cuvier assumed, as biological/anatomical principles, that organisms must be constructed so that they could successfully meet the conditions of their existence; that their parts formed a viable whole; and that there was a subordination of parts–the external, less fundamental organs showing the greatest variability, while more deep-seated ones were more constant in form. It appeared to Cuvier (1812) that there were four fundamental animal types, forming four *embranchments* of the animal kingdom. Each type (Vertebrata; Mollusca; Articulata; and Zoophytes and Radiata) was characterized by a particular mode of organization of the nervous system. Transmutation was not feasible, to Cuvier, because substantial departure from the original forms would lead to their being unviable in their conditions of existence.

Given the principle of subordination of parts, Cuvier's comparative anatomy yielded a rationale for his taxonomy. The peripheral organs and their differences provided a basis for the finer classificatory subdivisions of the animal kingdom, whereas differences in the more deep-seated organs revealed the more fundamental anatomical distinctions and taxonomic divisions, such as the four *embranchments*. Thus each animal contained within itself, so to speak, the indications of its proper place in the taxonomic hierarchy. In this respect, Cuvier's comparative anatomy and zoology were fundamentally different from the work of eighteenth century naturalists such as Linnaeus, which chiefly considered visible external characters. See also **Taxonomy (The History)**.

It was this difference that led Michel Foucault to declare that Cuvier's work was an essential precondition for the establishment of Darwin's biological evolutionism in that Cuvier emphasized the relationship between organisms and their environment. Further, he "ruptured" the "table" of the Linnaeans, which classified organisms by comparison of their external features, one with another, and in which organisms all formed part of one grand "plan." (Thus Linnaean natural history could hardly contemplate the independent modification of different parts of the taxonomic "table.") It was ironical, therefore, that Cuvier, the anti-evolutionist *par excellence*, should have been so important in preparing the way for Darwin. Against this, one might say that Lamarck proposed a transmutationist doctrine without Cuvier's help, and indeed in opposition to his views.

Cuvier's later work, notably his *Régne Animal* (1817), greatly expanded his earlier ideas and extended the range of information provided, but it was more synthetic in character, making available the rapidly growing knowledge of the animal world. Cuvier remained opposed to the idea that humans had existed before the last great catastrophe (which some of his contemporaries such as William Buckland sought to represent as the Noachian Flood). While some modern Creation Scientists base their thinking on Cuvier's "catastrophist" geology to a significant degree, he was not himself in any way a biblical fundamentalist and his science never invoked supernatural causes. Genesis, for Cuvier, had to be interpreted figuratively.

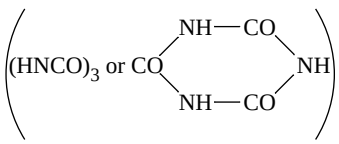
CYANAMIDES. Cyanamide [CAS: 420-04-2] $NC \cdot NH_2$ or HN:C:NH is a white solid, melting point 44 °C, boiling point 140 °C at 20 mm pressure, transformed at 150 °C into cyanuramide, (melamine [CAS: 2036-15-4]) tricyantriamide $(NC \cdot NH_2)_3$. Cyanamide reacts (1) as a base with strong acids forming salts, (2) as an acid forming metallic salts, such as calcium cyanamide $CaCN_2$. Cyanamide is formed (1) by reaction of cyanogen chloride $CN \cdot Cl$ plus ammonia (ammonium chloride also formed), (2) by reaction of thiourea plus lead hydroxide (lead sulfide also formed).

When calcium cyanamide [CAS: 56-62-7] is boiled with water, dicyandiamide $(NC \cdot NH_2)_2$, melting point 207 °C is formed (along with calcium hydroxide). Fusion of dicyandiamide with sodium carbonate plus carbon produces sodium cyanide plus ammonia (also some tricyantriamide). Diethylcyanamide $(C_2H_5)_2N \cdot CN$ is a colorless liquid, boiling point 189 °C at 748 mm pressure, and when hydrolyzed yields diethylamine $(C_2H_5)_2NH$ plus ammonia plus carbon dioxide. Diphenylcyanamide $C_6H_5N{:}C{:}NC_6H_5$ when hydrolyzed yields aniline plus carbon dioxide. Benzylcyanamide $C_6H_5CH_2NH \cdot CN$ is a white solid, melting point 43 °C.

CYANIC ACID AND RELATED COMPOUNDS. Cyanic acid, [CAS: 420-53-3] HCNO or HOCN, is a colorless, odorless liquid; soluble in water and in ether; volatile with decomposition when heated; passing at ordinary temperature into a mixture of cyanuric acid, [CAS: 108-80-5] $(HNCO)_3$, and cyamelide, $(CONH)_x$, white solid, which on vaporizing yields cyanic acid; when cyanic acid vapor is rapidly cooled in a freezing mixture, unstable, liquid cyanic acid is obtained, and when the vapor is condensed above 105 °C, cyanuric acid

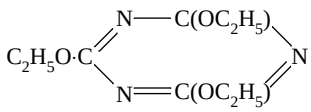


is obtained. Cyamelide dissolves in sulfuric acid unchanged and addition of water causes precipitation of cyamelide; passes into cyanuric acid when warmed with concentrated sulfuric acid, finally into carbon dioxide plus ammonia; dissolves in sodium hydroxide solution forming sodium cyanate. Sodium cyanate is prepared by heating sodium cyanide and an oxide such as lead monoxide, PbO, trilead tetroxide, Pb_3O_4, or lead dioxide, PbO_2, addition of water and separation of the sodium cyanate solution from the lead oxide by filtration. Sodium cyanate solution upon boiling changes into sodium carbonate plus urea, $CO(NH_2)_2$.

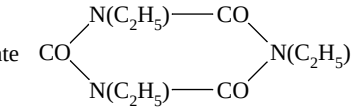
Ammonium cyanate, $CNONH_4$, white solid, formed by reaction of sodium cyanate and ammonium sulfate solutions, is transformed to urea upon being heated at 100 °C. This reaction was carried out in 1828 by Wöhler, and is the first record of a so-called inorganic substance being transformed outside a living organism into a so-called organic substance. The following esters are known:

Methyl isocyanate, CH_3NCO, boiling point 44 °C
Ethyl cyanate, C_2H_5OCN, decomposes on heating
Ethyl isocyanate, C_2H_5NCO, boiling point 60 °C
Phenyl isocyanate, C_6H_5NCO, boiling point 166 °C

Ethyl cyanurate



Ethyl isocyanurate



The extensive use of organic isocyanates in various industrial processes for production of high polymers has brought about tonnage production. Toluene diisocyanate is made by nitrating toluene to the dinitro compound, which is then reduced to the diamine, and treated with phosgene to obtain the diisocyanate:

$$C_6H_5CH_3 \xrightarrow{HNO_3} C_6H_3(NO_2)_2CH_3 \xrightarrow{H}$$

$$C_6H_3(NH_2)_2CH_3 \xrightarrow{COCl_2} C_6H_3(NCO)_2CH_3$$

Toluene diisocyanate is widely used in the manufacture of urethane plastics, particularly the urethane foamed plastics. Another isocyanate, diphenylmethane 4,4′-diisocyanate, is produced by reaction of aniline and formaldehyde, followed by reaction with phosgene:

$$2\ C_6H_5NH_2 \xrightarrow{HCHO} CH_2(C_6H_4HN_2)_2 \xrightarrow{COCl_2} CH_2(C_6H_4NCO)_2$$

The diphenylmethane 4,4′-diisocyanate is used in the manufacture of solid urethane elastomers (primarily for heavy-duty tires) and chemically resistant coatings.

Fulminic acid, HONC, and the fulminates are violently explosive. Utilizing this property, mercuric fulminate, $Hg(ONC)_2 \cdot \frac{1}{2}H_2O$, is used as a detonator for other explosives. Mercury fulminate is made by the reaction of ethyl alcohol and mercuric nitrate in excess of nitric acid, from which insoluble mercuric fulminate separates. Silver fulminate, Ag(ONC), is more explosive than mercuric fulminate, and is used in the manufacture of firecrackers. Free fulminic acid may be obtained by reaction of potassium fulminate and excess of ether. It volatilizes with the ether upon distilling, and changes rapidly to metafulminic acid. Related to fulminic acid is fulminuric acid, $(HONC)_3$, or $NO_2 \cdot CH(CN) \cdot CONH_2$.

CYANOGEN. [CAS: 460-19-5] Cyanogen $(CN)_2$ is a colorless gas of marked characteristic odor, very poisonous, density 1.8 (air equal to 1.0), melting point $-28\,^{\circ}C$, boiling point $-20\,^{\circ}C$, soluble. When passed into water at $0\,^{\circ}C$, cyanogen forms hydrocyanic acid plus cyanic acid, but at ordinary temperatures the reaction is complex. With sodium hydroxide solution, there is formed with cyanogen sodium cyanide plus sodium cyanate, with dilute sulfuric acid oxamic acid $COOH \cdot CONH_2$, oxalic acid $COOH \cdot COOH$. By reaction with tin and hydrochloric acid, cyanogen is reduced to ethylene diamine $CH_2 \cdot NH_2 \cdot CH_2 \cdot NH_2$. Cyanogen reacts with hydrogen to form hydrocyanic acid, and with metals, e.g., zinc, copper, lead, mercury, silver, to form cyanides. Cyanogen, (1) when burned in air produces a violet flame forming carbon dioxide and nitrogen in the outer part and carbon monoxide and nitrogen in the inner part, (2) when exploded with oxygen produces carbon dioxide or carbon monoxide and nitrogen depending upon the ratio of oxygen to cyanogen (2 volumes oxygen plus 1 volume cyanogen yields 2 volumes carbon dioxide plus 1 volume nitrogen; 1 volume oxygen plus 1 volume cyanogen yields 2 volumes carbon monoxide plus 1 volume nitrogen). The flame spectrum contains characteristic bands in the blue and violet. By means of the electric spark, the electric arc or a red hot tube, cyanogen is decomposed into carbon plus nitrogen. When heated at ordinary pressure at about $300\,^{\circ}C$, or under 300 atmospheres pressure at about 225°, cyanogen is converted into paracyanogen, a brown powder, also formed when mercuric cyanide is heated. Cyanogen is prepared (1) by reaction of sodium cyanide and copper sulfate solutions, whereby one half the cyanogen is evolved as cyanogen gas and one half remains as cuprous cyanide. From the filtered cuprous cyanide, by treatment with ferric chloride solution, cyanogen is evolved with accompanying formation of ferrous chloride, (2) by heating ammonium oxalate $COONH_4 \cdot COONH_4$ with phosphorus pentoxide, water being abstracted. Small amounts of cyanogen are present in blast furnace gas and raw coal gas.

CYANOHYDRINS. A cyanohydrin is an organic compound that contains both a cyanide and a hydroxy group on an aliphatic section of the molecule. Cyanohydrins are usually α-hydroxy nitriles which are the products of base-catalyzed addition of hydrogen cyanide to the carbonyl group of aldehydes and ketones. The IUPAC name for cyanohydrins is based on the α-hydroxy nitrile name. Common names of cyanohydrins are derived from the aldehyde or ketone from which they are formed.

The outstanding chemical property of cyanohydrins is the ready conversion to α-hydroxy acids and derivatives, especially α-amino and α,β-unsaturated acids. Because cyanohydrins are primarily used as chemical intermediates, data on production and prices are not usually published. The industrial significance of cyanohydrins is waning as more direct and efficient routes to the desired products are developed.

Cyanohydrins are usually colorless to straw yellow liquids with an objectionable odor akin to that of hydrogen cyanide. The lower molecular-weight cyanohydrins can be distilled under reduced pressure provided the cyanohydrin is kept at a slightly acidic pH.

Cyanohydrins can be formed by the acid- or base-catalyzed reaction of hydrogen cyanide with an aldehyde or ketone, the displacement of bisulfite ion by cyanide ion on the bisulfite addition compounds of aldehydes and ketones, or the exchange of cyanide ion between a ketone cyanohydrin and an aldehyde to give the usually more stable aldehyde cyanohydrin.

Cyanohydrins should be stabilized with acid to pH 3–4 to prevent decomposition to hydrogen cyanide and carbonyl compound. When cyanohydrins are shipped, steel drums, carboys, tank cars, and barges are used. In general, cyanohydrins are combustible liquids and many decompose upon heating. They should be stored in a cool, dry place, preferably outside and separated from other storage. Containers should be protected against physical damage.

Cyanohydrins are highly toxic by inhalation or ingestion, and moderately toxic through skin absorption. All α-hydroxy nitriles are potential sources of hydrogen cyanide or cyanides and must be handled with considerable caution. Contact with the skin and inhalation should be rigorously avoided. Special protective clothing should be worn and any exposure should be avoided. The area should be adequately ventilated. Immediate medical attention is essential in case of cyanohydrin poisoning.

Specific Compounds

Formaldehyde Cyanohydrin. This cyanohydrin, also known as glycolonitrile [CAS: 107-16-4], is a colorless liquid with a cyanide odor. It is soluble in water, alcohol, and diethyl ether. Equimolar amounts of 37% formaldehyde and aqueous hydrogen cyanide mixed with a sodium hydroxide catalyst at $2\,^{\circ}C$ for one hour give formaldehyde cyanohydrin in 79.5% yield.

Acetaldehyde Cyanohydrin. This cyanohydrin, commonly known as lactonitrile, is soluble in water and alcohol, but insoluble in diethyl ether and carbon disulfide. Lactonitrile is used chiefly to manufacture lactic acid and its derivatives, primarily ethyl lactate. Lactonitrile [CAS: 78-97-7] is manufactured from equimolar amounts of acetaldehyde and hydrogen cyanide containing 1.5% of 20% NaOH at -10–$20\,^{\circ}C$. The product is stabilized with sulfuric acid. Sulfuric acid hydrolyzes the nitrile to give a mixture of lactic acid [CAS: 598-82-3] and ammonium bisulfate. This mixture can be purified by adding methanol to form methyl lactate [CAS: 547-64-8] which is separated from the ammonium bisulfate. The methyl lactate is distilled, then hydrolyzed back to the aqueous acid. Removal of most of the water yields 90% lactic acid.

Acetone Cyanohydrin. This cyanohydrin, also known as α-hydroxyisobutyronitrile and 2-methyllactonitrile [CAS: 75-86-5], is very soluble in water, diethyl ether, and alcohol, but only slightly soluble in carbon disulfide or petroleum ether. Acetone cyanohydrin is the most important commercial cyanohydrin as it offers the principal commercial route to methacrylic acid and its derivatives, mainly methyl methacrylate [CAS: 80-62-6]. See also **Methacrylic Acid and Derivatives**. The principal U.S. manufacturers are Rohm and Haas Company, DuPont, CyRo Industries, and BP Chemicals.

Acetone cyanohydrin is used as a raw material for insecticides manufacture and also to produce ethyl α-hydroxyisobutryate [CAS: 80-55-7], a pharmaceutical intermediate. It has been used as a complexing agent for metals refining and separation.

Acetone cyanohydrin is manufactured by the direct reaction of hydrogen cyanide with acetone, catalyzed by base, generally in a continuous process.

Benzaldehyde Cyanohydrin. This cyanohydrin, also known as mandelonitrile [CAS: 532-28-5], is a yellow, oily liquid, insoluble in water, but soluble in alcohol and diethyl ether. Mandelonitrile is a component of the glycoside amygdalin [CAS: 29883-15-6], a precursor of laetrile [CAS: 1332-94-7] found in the leaves and seeds on most *Prunus* species (plum, peach, apricot, etc). In 1832, mandelonitrile was the first cyanohydrin to be synthesized. It is commercially prepared from benzaldehyde and hydrogen cyanide. Mandelonitrile is used by certain insects (tiger beetles, an African millipede) as a defense fluid. After expelling the fluid an enzyme catalyzes the conversion of mandelonitrile to benzaldehyde and HCN, which is usually fatal to the insect's enemy.

Ethylene Cyanohydrin. This cyanohydrin, also known as hydracrylonitrile or glycocyanohydrin [CAS: 109-78-4], is a straw-colored liquid miscible with water, acetone, methyl ethyl ketone, and ethanol, and is insoluble in benzene, carbon disulfide, and carbon tetrachloride. Ethylene cyanohydrin differs from the other cyanohydrins discussed here in that it is a β-cyanohydrin. It is formed by the reaction of ethylene oxide with hydrogen cyanide.

Synthetic Organic Chemicals, U.S. Production and Sales, 1989, USITC Publication 2338, USITC, Dec. 1990, section 15-4.

CYANOMETER. An instrument designed to measure or estimate the blueness of the sky. The type in most common use is the *Linke scale*. The *Linke scale* is simply a set of eight cards are numbered 2 to 16, the odd numbers to be used by the observer if he judges the sky color to lie between any of the given shades. Also called *blue-sky scale*.

CYANOMETRY. The study and measurement of the blueness of the sky. The characteristic blue color of clear skies is due to preferential scattering of the short wavelength components of visible sunlight by air molecules. Presence of foreign particles in the atmosphere alters the scattering processes in such a way as to reduce the blueness. Hence spectral analysis of diffuse sky radiation provides useful information concerning the scattering particles.

CYANOSIS. A blue color of the skin and mucous membranes, most marked in the lips, nose, cheeks, ears, hands, and feet. It is due to the presence of abnormally large amounts (in excess of 5% by weight) of reduced hemoglobin (i.e., hemoglobin which has given up its oxygen to the tissues) in the blood. This occurs when there is a failure of aeration of the blood as it passes through the lungs so that insufficient oxygen is picked up by the red cells, or in circulatory failure and stasis of venous blood in peripheral vascular beds. It also occurs when there is abnormal communication between the venous and arterial sides of the circulation as in certain congenital malformations of the heart. Cyanosis is commonly seen in severe heart disease, particularly the congenital type, pneumonia, severe infections, asthma, and emphysema. It is also seen as a result of poisoning with gases, or drugs which interfere with respiration or the rate of absorption of oxygen by the blood. It is also found in wool sorters' disease. For further mention of cyanosis, see specific diseases mentioned above.

CYBERNETICS. This term is derived from the Greek word meaning the science of the steering of ships. It was possibly first used in a broader sense by Ampere to mean the science of the control of society. The word was popularized in the modern sense as the result of the use of the term in a book by Norbert Wiener in 1948 which dealt with control in machines and in living systems. Possibly an acceptable definition of the term as currently used would be "the function of control in machines and animals." There has been a tendency in the United States to emphasize the control aspects, while in Europe, the emphasis has been on the handling of information. The science of control obviously involves three systems of work: (1) closed-loop feedback systems; (2) the manipulation of the information which guides these systems; and (3) processes for filtering out casual disturbances from the information channel. The second of these, obviously, and the third, less obviously, can lead on to a consideration of communication, control, and thought processes in animals. The term tends to be fuzzy because in its overall sense, cybernetics embraces numerous well-established disciplines already well covered by their own sets of definitions.

Thus, the concepts of feedback and closed-loop control systems are well advanced and covered in the general field of automatic control and instrumentation, as indeed are adaptive control systems, also sometimes ascribed to cybernetics. As one extends the application of these principles into biology and animal behavior, the interface with biophysics and molecular biology and associated fields is encountered. In recent years, formal dictionaries have greatly narrowed the definition of cybernetics to consider it a comparative study of computers and the animal nervous system in an attempt to understand the nature of the brain. See also **Control System**; and **Central and Peripheral Nervous Systems**.

CYBOTAXIS. A condition in which certain liquids, under x-ray examination, give evidence of structure resembling that of crystals. By passing a beam of x-rays through various alcohols and other organic liquids, G.W. Stewart and his collaborators have obtained one, two, or even three diffraction maxima or halos, somewhat like the diffraction rings produced by powdered crystals. These suggest that molecules are temporarily arranged in rows, layers, or stacks like bricks in a pile and that they have one, two, or even three different dimensions or spacings, corresponding, in accordance with Bragg's law, to the different angles of diffraction observed.

A closely related property is exhibited by certain substances known as "liquid crystals," which appear to be intermediate between merely cybotactic liquids and true crystals. In these there appear to be large groups of molecules which, though able to move and turn about, retain their structural arrangement. Such mesomorphic substances manifest even some of the optical properties of crystals, which the former type do not.

See also **Liquid Crystals**.

CYCAD *(Cycadales).* An order of Gymnosperms containing 9 genera and less than 100 species. They first appeared in late Paleozoic times, became a dominant group almost cosmopolitan in distribution in the Mesozoic period. Cycads are now limited to tropical or subtropical regions, often with a very restricted range. Some of the genera are found only in Mexico and the West Indies; others occur only in Australia, Africa and various islands of the Pacific Ocean. Because of their decorative habitat they are frequently grown in cultivation in places outside their natural range. Many are grown as greenhouse plants in temperate regions.

The appearance of the plants is uniform in all genera. Stems are subterranean and tuberous, or above ground and columnar. Columnar stems are usually from 6–10 feet (1.8 to 3 meters) tall, but some species grow much higher. The leaves form a large crown at the top of the stem. See Fig. 1. They are pinnate except in one Australian genus, *Bowenia*, which has bipinnate leaves which are thick and leathery. The stems are generally thickly clothed in the persistent leaf-bases, which sometimes give an indication of the age of the plants. As determined by the number of leaf-bases many are several hundred years old. Internally, the stem contains a very large pith and a thick cortex with a narrow cylinder of vascular tissues between them. The primary root is large and extends deep into the ground.

All *Cycads* are dioecious plants. The ovulate strobili, or cones, are usually very large. The different genera have cones which show a very distinct series, ranging from those of *Cycas revoluta* with loosely arranged leaf-like sporophylls to the compact cones of *Zamia*. See Fig. 2. The large ovules, or megasporangia, are covered by a single thick integument. The male cones are much smaller and always formed of compactly massed sporophylls, each of which bears many sporangia, or pollen sacs. The pollen grains are very numerous and light. Pollination is effected by wind, though insects are frequently seen on the male cones, and may play some part in the pollen transfer.

The pollen grains are caught in a sticky fluid, which covers the micropyle of the ovule. As this sticky substance dries, it shrinks, drawing the pollen grains down through the micropyle. Each pollen grain then puts out a pollen tube which digests its way through the mass of nucellar tissue which surrounds the female gametophyte, and reaches a small chamber which is formed at the micropylar end of the gametophyte and the nucellus. Meanwhile, two sperm cells have been forming in the pollen tube. Each is very large and has a spiral band of cilia wound about its anterior end. Freed from the pollen tube, these sperm pass to the gametophyte, where

Fig. 1. Cycas, a cycad. A male plant, shown at left, bears a single, large staminate cone. Female plant, on right, bears a cluster of megasporophylls in a loosely arranged cone. (*A.M. Winchester*.)

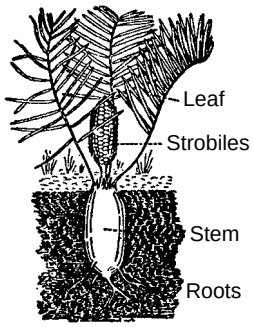

Fig. 2. A cycad, a mature sporophyte of *Zamia* bearing a carpellate strobile.

union of one sperm with the egg occurs. Sperm and egg nucleus presently unite, and the egg is fertilized. The fertilized egg divides to form a mass of cells known as the proembryo. At the base of this proembryo is a group of cells which becomes the true embryo. The mature seed of a Cycad has an outer fleshy coat, which is variously colored. Inside this there is a hard stony layer which in turn surrounds another layer which is fleshy at first but soon becomes thin and dry. Within is the gametophyte, which contains the embryo. Cycad seeds germinate as soon as they are mature.

Apart from their value as decorative plants or as curiosities, few products of importance are obtained from the Cycads. Their leathery leaves remain green for some time after removal from the plant. They are therefore often used on Palm Sunday and for funeral purposes. The seeds of many of them are edible, as is also the central portion of the stem of *Cycas* species. Cycads are sometimes confused with palms.

Cycads probably originated in very early times from some primitive ferns. Even today certain cycads closely resemble ferns. Cycads are "living fossils" which continue to exist in a very restricted range.

CYCLAMATE. See **Sweeteners**.

CYCLE EFFICIENCY. The efficiency of a given cycle in an internal combustion engine, in producing work, expressed as the useful work output divided by the work input. For a gas-turbine engine, the cycle efficiency is the useful work energy less the work required for compression divided by the heat energy in the fuel used; for a reciprocating engine, it is the energy of the indicated horsepower divided by the heat energy of the fuel.

CYCLE (Mechanical). A series of changes executed in orderly sequence, by means of which a mechanism, a working substance, or a system is caused periodically to return to the same initial condition, constitutes a cycle. Many complicated machines or assemblages of machines work in definite cycles. An important form of cycle is the heat engine cycle, in which a series of thermodynamic changes in a working medium periodically return the system to the same thermodynamic level. This working medium may be a gas, as in the Otto and Diesel cycles, or a vapor, as in the steam cycle. See also **Carnot cycle**, for an example of a general ideal cycle. A vapor cycle is so named from the fact that it is conceived as using the same vapor over and over, passing it around what might be thought of as a closed loop of equipment, and subjecting it to various thermodynamic changes by means of which useful mechanical energy is produced from heat. The distinction between vapor and engine cycle should be recognized. An engine cycle considers only the changes occurring within an engine, but a vapor cycle involves, in addition, all changes in the vapor state from the point of leaving the engine until it is again ready to enter it.

CYCLE OF STRESS. The stress variation on a particular plane through a specific point in a body which is subjected to a repeated load is called a cycle of stress. If the stress varies alternately between tension and compression, the variation is known as reversal of stress. The reversal is complete when the alternate stresses are equal in magnitude.

The algebraic difference between the maximum and minimum stresses of a cycle is the range of stress. The endurance limit depends on the range of stress.

CYCLIC CODE. In computer operations, a positional notation, not necessarily binary, in which quantities differing by one unit are represented by expressions, which are identical except for one place or column, and the digits in that place or column differ by only one unit. Also called *reflected code*.

CYCLIC CURVE. A general class of higher plane curves of which there are many special cases. Consider two circles, one designated as C, which is of radius R, and fixed in a Cartesian coordinate system; the other, C' of radius r, which moves in contact with C. Place the center of C at the coordinate origin, the center of C' on the OX-axis and select a point P on this axis at a distance a from the center of C'. As the latter rolls around the circumference of C the point P will generate a curve given in parametric form by the equations

$$x = (R + r)\cos\phi - a\cos\frac{(R + r)\phi}{r}$$

$$y = (R + r)\sin\phi - a\sin\frac{(R + r)\phi}{r}$$

where the angle ϕ is measured from the coordinate origin. If P is inside or outside the rolling circle ($a \lessgtr r$), the curve is called trochoidal; if $a = r$, so that the point P is on the circumference of the rolling circle, the curve is cycloidal. Furthermore, the two radii can be so related that C' is always on the outside of C and the curves are then epitrochoidal or epicycloidal; if C' rolls around the inside of C the curves are hypotrochoidal or hypocycloidal.

In further special cases, when C' rolls along a plane instead of around another circle, the curve is called a trochoid or a cycloid. Still another special case is the evolute of a circle.

A generalized cyclic curve is produced when the circles are replaced by ellipses or hyperbolas. A pseudocyclic curve involves hyperbolic functions instead of trigonometric functions.

See also **Curve (Higher Plane)**.

CYCLOHEXANOL-CYCLOHEXANONE. Cyclohexanol [CAS: 108-93-0] is a colorless, viscous liquid with a camphoraceous odor. It is used chiefly as a chemical intermediate, a stabilizer, and a homogenizer for various soap detergent emulsions, and as a solvent for lacquers and varnishes. Cyclohexanol was first prepared by the treatment of 4-iodocyclohexanol with zinc dust in glacial acetic acid, and later by the catalytic hydrogenation of phenol at elevated temperatures and pressures.

Cyclohexanone [CAS: 108-94-1] is a colorless, mobile liquid with an odor suggestive of peppermint and acetone. Cyclohexanone is used chiefly as a chemical intermediate and as a solvent for resins, lacquers, dyes, and insecticides. Cyclohexanone was first prepared by the dry distillation of calcium pimelate [CAS: 19455-79-9], $O{-}OC(CH_2)_5COO^{-}Ca^{2+}$, and later by Bouveault by the catalytic dehydrogenation of cyclohexanol.

Cyclohexanol is miscible in all proportions with most organic solvents, including those customarily used in lacquers. It dissolves many oils, waxes, gums, and resins.

Cyclohexanone is miscible with methanol, ethanol, acetone, benzene, *n*-hexane, nitrobenzene, diethyl ether, naphtha, xylene, ethylene glycol, isoamyl acetate, diethylamine, and most organic solvents. This ketone dissolves cellulose nitrate, acetate, and ethers, vinyl resins, raw rubber, waxes, fats, shellac, basic dyes, oils, latex, bitumen, kaure, elemi, and many other organic compounds.

Cyclohexanol is produced commercially by the catalytic air oxidation of cyclohexane or the catalytic hydrogenation of phenol. The oxidation of cyclohexane to a mixture of cyclohexanol and cyclohexanone, known as KA-oil (ketone–alcohol, cyclohexanone–cyclohexanol crude mixture), is used for most production. The earlier technology that used an oxidation catalyst such as cobalt naphthenate [CAS: 61789-51-3] at 180–250 °C at low conversions has been improved. Cyclohexanol can be obtained through a boric acid-catalyzed cyclohexane oxidation at 140–180 °C with up to 10% conversion. Unreacted cyclohexane is recycled and the product mixture is separated by vacuum distillation. The hydrogenation of phenol to a mixture of cyclohexanol and cyclohexanone is usually carried out at elevated temperatures and pressure in either the liquid or in the vapor phase catalyzed by nickel.

Cyclohexanone is produced commercially by the catalytic hydrogenation of phenol or by the catalytic air-oxidation of cyclohexane; and may be prepared by either the catalytic dehydrogenation or oxidative dehydration

of cyclochexanol. The hydrogenation of phenol to cyclohexanone is the most efficient route. This process can be carried out either in the liquid phase, catalyzed by palladium on carbon, or in the vapor phase, catalyzed by palladium on alumina. Of the two processes, the liquid phase is more selective and requires much less catalyst inventory. Allied Signal Corp. operates an inherently safe liquid-phase phenol hydrogenation process at temperatures below the atmospheric boiling point of the reaction liquids, permitting over 99% selectivity at 90% conversion.

Vapor-phase oxidation of cyclohexane is commercially feasible, but the preferred route is liquid-phase cyclohexane oxidation. In the latter process, conversions are usually below 10%. The product is a mixture of cyclohexanone and cyclohexanol which may be separated by distillation or converted to cyclohexanone by dehydrogenation over either zinc oxide or nickel or magnesium oxide. Mild oxidation of cyclohexanol to cyclohexanone can be carried out with or without catalyst.

Cyclohexanol shows most of the typical reactions of secondary alcohols. It reacts with organic acids to form esters, and with halogen acids to form the corresponding halides. Dehydrating agents convert cyclohexanol into cyclohexene [CAS: 110-83-8]. Cyclohexanone shows most of the typical reactions of aliphatic ketones.

The most important use of cyclohexanone is as a chemical intermediate in nylon manufacture; 97% of all cyclohexanone output is used either to make caprolactam for nylon-6, or adipic acid for nylon-6,6.

Cyclohexanol is slightly toxic by the oral route of exposure and is slightly irritating to the skin. It can cause severe eye irritation and transient corneal injury.

The ACGIH threshold limit value (TLV), time-weighted average for an 8-h workday, 40-h workweek, was set at 50 ppm ($\sim$ 200 mg/m^3) with a notation for skin absorption.

Cyclohexanone has only slight toxicity by the oral, dermal, and inhalation routes of exposure. Liquid or vapor exposures may result in transient corneal injury. Primary irritation and defatting of the skin can result from substantial or prolonged contact with cyclohexanone. Exposure to high vapor concentrations can cause central nervous system (CNS) depression, an effect which can also occur after ingestion or repeated dermal exposure.

The time-weighted average OSHA permissible exposure limit (PEL), as well as the ACGIH threshold limit value (TLV), for cclohexanone is 25 ppm (100 mg/m^3) with a notation for skin absorption.

The precautions usually observed when handling volatile solvents should be observed as a matter of course with cyclohexanone and cyclohexanol. These include adequate and proper ventilation, avoidance of prolonged breathing of vapor or contact of the liquid with the skin, avoidance of internal consumption, and protection of the eyes against splashing liquids.

CYCLOID. The path described by a point on a circle as it rolls along a straight line and a special case of a trochoid (see also **Cyclic Curve**). Thus b, the distance of the generating point from the center of the rolling circle equals a, the radius of the circle. Its parametric equations are $x = a(\theta - \sin\theta)$; $y = a(1 - \cos\theta)$ and in Cartesian coordinates $x = a\cos^{-1}(a - y)/a + \sqrt{y(2a - y)}$. There are cusps in the curve, separated by the distance $2\pi a$, every time the point touches the line on which the circle rolls. See Fig. 1.

The teeth of gears are often cut with faces which are arcs of cycloids, so that there is rolling contact when the gears are in mesh.

The inverted arch of the cycloid is a tantochrone for the force of gravity and a brachistochrone, or curve of quickest descent. The evolute of a cycloid is another cycloid. A related curve, sometimes called the companion of the cycloid is $x = a\theta$, $y = a(1 - \cos\theta)$.

See also **Tantochrone**; and **Trochoid**.

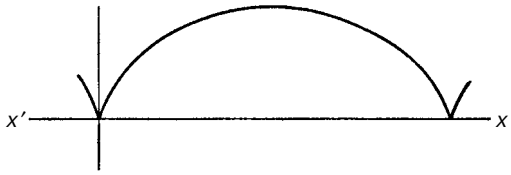

Fig. 1. Cycloid.

CYCLONES. Cyclones are hazardous weather conditions characterized by extreme gusts of wind moving in a circular pattern, low pressure, and intense rain. They form over tropical or subtropical waters; however, some can reach land, where they have in the past inflicted great amounts of damage on buildings and communities.

Based on wind strength, cyclones are given various names. Tropical depressions have maximum surface winds of less than 39 mph. Those cyclones whose maximum winds are between 39 and 74 mph are known as tropical storms. Upon attaining 74-mph surface winds, a cyclone is known as one of a number of names that are all regional equivalents of the same type of storm.

The names of cyclones are typhoon (in the NW Pacific Ocean), hurricane (in the North Atlantic, NE Pacific, and South Pacific Ocean), tropical cyclone (in the SW Indian Ocean), severe cyclonic storm (in the North Indian Ocean), and severe tropical cyclone (in the SW Pacific and SE Indian Oceans). Cyclones always build over tropical seas. There are seven basins in which the majority of tropical cyclones form: the Atlantic Basin, the North Indian Basin, the Southwest Indian Basin, the Southeast Indian-Australian Basin, the Australian-Southwest Pacific Basin, the Northwest Pacific Basin, and the Northeast Pacific Basin. Heat gives cyclones their energy, and thus the water over which a cyclone forms must be at least as warm as 80 °F (27 °C) i.e., tropical. Other conditions necessary for a cyclone include a fast cooling atmosphere, moisture in the middle troposphere area, a distance of more than 300 miles (483 km) from the equator to be influenced by the Coriolis force, and minimal vertical wind shear. This vertical wind shear is the result of differences between winds in the lower and upper portions of the atmosphere. However, the main contributor to the formation of a cyclone is a disturbance in the form of a thunderstorm or group of showers. When all of these factors come together, conditions are right for a tropical cyclone, although the presence of each of these factors does not guarantee the formation of a cyclone. Cyclones are spontaneous; a minute variation in one variable can be the difference between a hurricane and a thunderstorm. See also **Atmosphere (Earth)**; and **Fronts and Storms**.

The circular area in the center of a cyclone, known as the "eye," has conditions quite different from those in the region surrounding it. Calmness and a light breeze characterize the eye. Temperatures are generally higher than those in the surrounding area, and the sky is usually very clear.

Since the 1970s, cyclones have been regularly named by various people and agencies, depending on where the cyclones originated. They are named to ensure ease of description among newscasters, weather people, and the general public. Names are often taken from rotating lists, one name for each letter of the alphabet.

In the Atlantic basin, tropical cyclone names are "retired" (that is, not to be used again for a new storm) if it is deemed to be quite noteworthy because of the damage and/or deaths it caused. This is to prevent confusion with a historically well-known cyclone with a current one in the Atlantic basin. See Table 1 for the list of names that have been retired and the year of the storm in question.

Strong cyclones often cause extensive damage to whatever they encounter. Damage can range from crop destruction to total devastation of building structures, depending on the severity of the cyclone. They become most dangerous as they hit land and spawn tornadoes. These are formed when tropical cyclones begin to lose their power. The diameter of a tropical cyclone is measured in kilometers; the diameter of a tornado is measured in meters. In 1980, one of the most destructive cyclone-spawned tornadoes in the United States caused nearly $100,000,000 worth of damage to the Austin, Texas, area. Along with destruction, cyclones (and the subsequent tornadoes) cause death. Large objects lifted from the path of the extreme wind are tossed about like lethal weapons. In 1964, twenty-two people were killed by a tornado that hit the Los Angeles area in the United States. The most damaging cyclone in history was Hurricane Katerina (2005), which caused over $165 billion in damage to the Southern United States. The

TABLE 2. SAFFIR-SIMPSON

Saffir-Simpson Category	Maximum sustained wind speed			Minimum central pressure	Storm surge	
	mph	m/s	kts	mb	ft	m
1	74–95	33–42	64–82	>980	3–5	1.0–1.7
2	96–110	43–49	83–95	979–965	6–8	1.8–2.6
3	111–130	50–58	96–113	964–945	9–12	2.7–3.8
4	131–155	59–69	114–135	944–920	13–18	3.9–5.6
5	156+	70+	136+	<920	19+	5.7+

Note: Classification by central pressure was ended in the 1990s, and wind speed alone is now used. These estimates of the central pressure that accompany each category are for reference only. These surge values are for reference only. The actual storm surge experienced will depend on offshore bathymetery and onshore terrain and construction.

most deadly cyclone ever may have been the Bangladesh Cyclone, which killed at least 300,000 people in 1970. One of the ways in which a hurricane will cause damage is through the storm surge. This is the name given to the phenomenon whereby sea level in the area of a cyclone rises due to cyclonic winds.

Once a cyclone reaches 74 mph maximum winds and is considered a hurricane, it's intensity is rated by the Saffir–Simpson Scale, Table 2, used since the 1970s by the National Oceanic and Atmospheric Administration (NOAA).

Cyclones can range from relatively simple tropical storms to devastating hurricanes whose winds swirl at furious speeds. Their effects can be disastrous and long-lasting (Table 3).

Tropical Cyclone Names

Tropical cyclones are named to provide ease of communication between forecasters and the general public regarding forecasts, watches, and warnings. Since the storms can often last a week or longer and that more than one can be occurring in the same basin at the same time, names can reduce the confusion about what storm is being described. According to Dunn and Miller , the first use of a proper name for a tropical cyclone was by an Australian forecaster early in the 20th century.

During World War II, tropical cyclones were informally given women's names by US Army Air Corp and Navy meteorologists (after their girlfriends or wives) who were monitoring and forecasting tropical cyclones over the Pacific. From 1950 to 1952, tropical cyclones of the North Atlantic Ocean were identified by the phonetic alphabet (Able-Baker-Charlie-etc.), but in 1953 the US Weather Bureau switched to women's names. In 1979, the WMO and the US National Weather Service (NWS) switched to a list of names that also included men's names.

The Northeast Pacific basin tropical cyclones were named using women's names starting in 1959 for storms near Hawaii and in 1960 for the remainder of the Northeast Pacific basin. In 1978, both men's and women's names were utilized.

The Northwest Pacific basin tropical cyclones were given women's names officially starting in 1945 and men's names were also included beginning in 1979. Beginning on 1 January 2000, tropical cyclones in the Northwest Pacific basin are being named from a new and very different list of names. The new names are Asian names and were contributed by all the nations and territories that are members of the WMO's Typhoon Committee. These newly selected names have two major differences from the rest of the world's tropical cyclone name rosters. One, the names by and large are not personal names. There are a few men's and women's names, but the majority are names of flowers, animals, birds, trees, or even foods, etc, while some are descriptive adjectives. Secondly, the names will not be allotted in alphabetical order, but are arranged by contributing nation with the countries being alphabetized.

The North Indian Ocean region tropical cyclones are not named.

The Southwest Indian Ocean tropical cyclones were first named during the 1960/1961 season.

The Australian and South Pacific region (east of 90E, south of the equator) started giving women's names to the storms in 1964 and both men's and women's names in 1974/1975.

Northern Hemisphere

For a list of the upcoming tropical cyclone names, see Table 4 *Contributed by Chris Landsea and the National Hurricane Center*.

Since 1978, the United Nations' World Meteorological Organization, a group representing some 120 different countries, has used pre-determined lists of names for tropical storms for each ocean basin of the world. The Atlantic basin, which falls under Regional Association IV, has a six year supply of names with 21 names for each year. Why 21 names? Well, the letters Q, U, X, Y and Z are not used because names beginning with those letters are in short supply (you would need at least 3 male and 3 female names for each letter, plus a back-up supply for those retired). Think about it; how many men and women do you know whose names begin with these letters?

In the Atlantic and East Pacific, if they have run through the list they then used the Greek alphabet : Alpha, Beta, Gamma, Delta,... etc. So if they ever have a Hurricane Omega you know it's been a busy year. At the present time there is no provision for retiring any of the Greek alphabet names, should one be so terrible as to be excluded. Fortunately, Tropical Storms Alpha and Beta in 2005 have been the only use of this option.

In the Central and West Pacific they have a perpetual lists of names, so when one list is through they simply start on the next.

TABLE 3. DAMAGE CAUSED BY CATEGORY 1–5 STORMS

Category	Level	Description	Example
1	MINIMAL	Damage primarily to shrubbery, trees, foliage, and unanchored homes. No real damage to other structures. Some damage to poorly constructed signs. Low-lying coastal roads inundated, minor pier damage, some small craft in exposed anchorage torn from moorings.	Hurricane Earl (1998)
2	MODERATE	Considerable damage to shrubbery and tree foliage; some trees blown down. Major damage to exposed mobile homes. Extensive damage to poorly constructed signs. Some damage to roofing materials of buildings; some window and door damage. No major damage to buildings. Coast roads and low-lying escape routes inland cut by rising water 2 to 4 hours before arrival of hurricane center. Considerable damage to piers. Marinas flooded. Small craft in unprotected anchorages torn from moorings. Evacuation of some shoreline residences and low-lying areas required.	Hurricane Georges (1998)
3	EXTENSIVE	Foliage torn from trees; large trees blown down. Practically all poorly constructed signs blown down. Some damage to roofing materials of buildings; some wind and door damage. Some structural damage to small buildings. Mobile homes destroyed. Serious flooding at coast and many smaller structures near coast destroyed; larger structures near coast damaged by battering waves and floating debris. Low-lying escape routes inland cut by rising water 3 to 5 hours before hurricane center arrives. Flat terrain 5 feet of less above sea level flooded inland 8 miles or more. Evacuation of low-lying residences within several blocks of shoreline possibly required.	Hurricane Fran (1996)
4	EXTREME	Shrubs and trees blown down; all signs down. Extensive damage to roofing materials, windows and doors. Complete failures of roofs on many small residences. Complete destruction of mobile homes. Flat terrain 10 feet of less above sea level flooded inland as far as 6 miles. Major damage to lower floors of structures near shore due to flooding and battering by waves and floating debris. Low-lying escape routes inland cut by rising water 3 to 5 hours before hurricane center arrives. Major erosion of beaches. Massive evacuation of all residences within 500 yards of shore possibly required, and of single-story residences within 2 miles of shore.	Hurricane Betsy (1965)
5	CATASTROPHIC	Shrubs and trees blown down; considerable damage to roofs of buildings; all signs down. Very severe and extensive damage to windows and doors. Complete failure of roofs on many residences and industrial buildings. Extensive shattering of glass in windows and doors. Some complete building failures. Small buildings overturned or blown away. Complete destruction of mobile homes. Major damage to lower floors of all structures less than 15 feet above sea level within 500 yards of shore. Low-lying escape routes inland cut by rising water 3 to 5 hours before hurricane center arrives. Massive evacuation of residential areas on low ground within 5 to 10 miles of shore possibly required.	Hurricane Camille (1969)

Note that tropical storms are not on this scale, but can produce extensive damage with rainfall-produced flooding. Note also that category 3, 4, and 5 hurricanes are collectively referred to as major (or intense) hurricanes. These major hurricanes cause over 83% of the damage in the USA even though they account for only 21% of tropical cyclone landfalls. (Landsea, C.W.): "A climatology of intense (or major) Atlantic hurricanes" *Mon. Wea. Rev.*, **121**, 1703–1713 (1993).

Each year the next name is just the one following the last from the previous year. Once through a list the next name will be off of the top of the next list.

Northwest Pacific

For over a half-century (since at least 1945) the military weather forecasters, initially members of the U. S. Navy and later also from the U. S. Air Force, have named tropical cyclones forming in the Northwest Pacific basin. The names utilized were almost exclusively English feminine names through 1978, but beginning in 1979 men's names were used with women's names in an alternating fashion. Also, starting in 1963 the meteorological service of the Philippines (now known as PAGASA) began assigning Filipino women's names ending in "ng" to tropical depressions and cyclones forming in or passing through PAGASA's area of warning responsibility. In 2002 a new naming scheme was adopted by PAGASA (see below).

Beginning on 1 January 2000, tropical cyclones in the Northwest Pacific basin are named from a new and very different list of names. The new names are Asian names and were contributed by all the nations and territories that are members of the WMO's Typhoon Committee. The new names will be allotted to developing tropical storms by the Tokyo Typhoon Centre of the Japanese Meteorological Agency which is the RSMC for the basin. See Table 5, *Contributed by Gary Padgett, NOAA.*

These newly selected names have two major differences from the rest of the world's tropical cyclone name rosters. One, the names by and large are not personal names. There are a few men's and women's names, but the majority are names of flowers, animals, birds, trees, or even foods, etc, while some are descriptive adjectives. Secondly, the names will not be allotted in alphabetical order, but are arranged by contributing nation with the countries being alphabetized. Fourteen nations or territories contributed ten names each for a total of 140 names. The first 42 names on the roster are:

PAGASA Names.

Since 1963 PAGASA has independently named tropical cyclones forming in the Philippines' AOR — from 115E to 135E and from 5 N to 25 N (except for a portion of the northwestern corner of the above region). Even though the Philippines contributed ten names to the international list of typhoon names, PAGASA still continues to assign their own names for local use within the Philippines. It is felt that familiar names are more easily remembered in the rural areas and that having a PAGASA- assigned name helps to underscore the fact that the cyclone is within PAGASA's AOR and potentially a threat to the Philippines. Another consideration may be PAGASA's desire to assign a name when a system is first classified as a tropical depression. Since tropical and/or monsoon depressions can bring very heavy rainfall to the nation which often results in disastrous flooding, the weather service feels that assigning a name helps to enhance public attention given to a system. Beginning with 2001 PAGASA began using new sets of cyclone names. These do not all end in "ng" as did the older names. Four sets of 25 names will be rotated annually; thus, the set for 2002 will be re-used in 2006. In case more than 25 systems are named in one season, an auxiliary set will be used. See Table 6, *Contributed by Gary Padgett, NOAA.*

See Table 7 for the Indian Ocean Cyclone names and Tables 8–10, for the Southern Pacific Cyclone names. *Contributed by Julian Heming, Jack Beven, Gary Padgett, Frank Woodcock and Jon Gill, NOAA.*

If a tropical cyclone moves from the Atlantic regions to the Northeast Pacific, or vice versa the old rule used to be that if the tropical storm or hurricane moved into a different basin, then it was renamed to whatever name was next on the list for the area. The last time that this occurred was in July 1996 when Atlantic basin Hurricane Cesar moved across Central America and was renamed Northeast Pacific basin Hurricane Douglas. The

NOTE: The name of a new cyclone is determined by sequentially cycling through lists A, B, C and D, then starting list A again. Names from the standby list E are used as replacements when necessary.

last time that a Northeast Pacific system moved into the Atlantic basin was in June 1989 when Cosme became Allison.

However, these rules have now changed at the National Hurricane Center and if the system remains a tropical cyclone as it moves across Central America, then it will keep the original name. Only if the tropical cyclone dissipates with just a tropical disturbance remaining, will the National Hurricane Center give the system a new name assuming it becomes a tropical cyclone once again.

Australian Tropical Cyclones

An estimate of cyclone severity is now included in all tropical cyclone advices. The table below provides information concerning effects due to wind which are typical of cyclones in the various categories. Remember that the system is not designed to give an exact statement of conditions at individual locations but will give a general idea of the expected worst conditions. Categories of cyclone severity range from "1" for weak cyclones to "5" for the most severe cyclones. Accordingly, the risk of property and crop damage, shore erosion and danger to life increases from low for a category 1 to very high for a category 5 cyclone. Using this severity scale, communities will be able to assess the degree of cyclone threat and take appropriate action. It must be emphasised that the category refers to the severity in the zone of maximum winds and therefore the effects felt at individual locations may not be exactly as described in the accompanying table.

Damage will vary from location to location depending upon factors such as:

- how far you are from the zone of maximum winds
- how exposed the location is

NOTE: When a cyclone is located or is expected to be located such that two or more tropical cyclone warning centres are involved, every attempt is made to resolve any differences of opinion on the cyclone and its expected behavior through discussions. After discussion, the decision of the warning centre with prime responsibility prevails. The warning centre with prime responsibility for the cyclone issues the warning for that cyclone. The warning includes all regions affected by the tropical cyclone, even when these extend into another centre's area of responsibility.

- building standards
- vegetation type
- resultant flooding

It should also be noted that the category does not refer to storm tides; if a storm tide is expected it will be mentioned separately in the cyclone warning.

Cyclone Severity Categories - From the Australian Bureau of Meteorology are given in Table 11.

TABLE 11. TROPICAL CYCLONE SEVETITY

Categories	Winds	Typical effects (indicative only)
Category 1	Strongest gust less than 125 km/h (Less than 78 mi/h)	Negligable house damage. Damage to some crops, trees and caravans. Draft may drag moorings.
Category 2	Strongest gust 125 — 170 km/h (78 — 106 mi/h)	Minor house damage. Significat damage to signs, trees and caravans. Heavy damage to some crops. Risk of power failure. Small craft may break moorings.
Category 3 (eg, Winifred)	Strongest gust 170 — 225 km/h (106 — 140 mi/h)	Some roof and structural damage. Some caravans destroyed. Power failure likely.
Category 4 (eg, Tracy)	Strongest gust 225 — 280 km/h (140 — 174 mi/h)	Significant roofing loss and structural damage. Many caravans destroyed and blown away. Dangerous airborne debris. Widespread power failure.
Category 5 (eg, Orson)	Strongest gust More than 280 km/h (More than 174 mi/h) Extremely dangerous with widespread destruction.

CYCLONE WAVE. 1. A disturbance in the troposphere of wave length 1000–4000 km (cyclonic scale). They are recognized on synoptic charts as migratory high and low pressure systems. These waves have been identified with the unstable perturbations discussed in connection with baroclinic instability and shearing instability. See also **Baroclinic Instability**; **Barotropic Disturbance**; and **Short Wave**.

2. A frontal wave at the crest of which there is a center of cyclonic circulation; therefore, the frontal wave of a wave cyclone.

CYCLONIC. Having a sense of rotation about the local vertical the same as that of the Earth's rotation: that is, as viewed from above, counterclockwise in the Northern Hemisphere, clockwise in the Southern Hemisphere, undefined at the equator; the opposite of anticyclonic.

CYCLOPHON. A name given to a generic type of vacuum tube utilizing a beam of electrons as a switching or commutating element.

CYCLOSTOMATA. The round-mouthed eels, hag fishes, and lampreys. A class of the phylum Chordata made up of marine and fresh-water species resembling slender fishes in form but without hinged jaws, and having a protrusible toothed tongue, single nostril on top of head, and naked glandular skin.

The principal characters of the class are as follows. (1) The notochord is persistent. (2) Cartilaginous neural arches indicate the development of a vertebral column. (3) There are no paired fins. (4) The mouth is a funnel-shaped depression with chitinous (see **Chitin**) teeth. (5) External gill openings are separate.

The two principal subdivisions of the class are listed both as subclasses and as orders in modern classifications.

Subclass *Myxinoidea (Hyperotreta)*. The hag fishes. Marine species with a poorly developed oral depression. Gill openings far behind head.

Subclass *Petromyzontia (Hyperoartia)*. Lampreys. Marine and fresh-water species with a well-developed oral funnel acting as a sucker. Gill openings immediately behind head.

It is fairly probable that the origins of the jawless fishes can be found in brackish water, i.e., in the intermediate region between salt water and fresh water with its high variations in water temperature, salinity, water flow, depth, and other characteristics — all of which accelerate an adaptation process. Some structural features of the cyclostomes were present primevally and others have been modified as a result of the cyclostome life habits.

The distribution of jawless fishes is limited to the temperate-to-cold waters of the northern and southern hemispheres. The northern species are more highly differentiated from the southern ones than those in the same hemisphere. Water temperature is an important factor in distribution of the sea-living hagfishes. The 10 °C boundary is crucial for them. In the cold northern and southern seas hagfishes can penetrate to approximately 100 feet (30 meters), while at the equator they are found at depths of over 3280 feet (1000 meters).

Hagfishes (Myxinoidea). These are worm-shaped jawless fishes with nasal opening lying at the fore-end of the body joined with the mouth opening. The species has 4 to 6 barbels on the head; the mouth has 2 rows of protruding teeth and a row of mucous glands are on each side of the stomach. A single fin seam is present and the cartilage gill skeleton is poorly developed. Hagfishes have underdeveloped eyes which are not visible externally. They are pure sea inhabitants, and they lay only a few large eggs which in development lack a larval stage. The hagfish eye is covered by skin and has neither lens, iris, nor muscles, and the corresponding connections to the brain are poorly developed. Experiments have shown that this eye has no particular visual significance; interestingly, light-sensitive organs have been found in the skin, especially in the head and rear regions. A similar condition exists in other boring and hole-inhabiting animals.

Aquarium experiments have shown that common hagfishes become active immediately after some bait has been laid and can find it within 2 minutes. Little is known about distances from which food can be detected, but on the basis of some observations this would amount to 20 to 24 inches (50 to 60 centimeters). Large numbers of hagfishes collect around a good-sized piece of food after a short time. In one case, 123 hagfishes were found at a dead cod; and another time 100 had collected at a bait. Dead animals are quickly devoured by hagfishes. However, there is not a sufficient number of dead fishes or other organisms lying on the ocean floor to serve as the prime food source for larger hagfish populations. Extensive investigations have shown that the main hagfish diet does not consist of carrion, but of organisms inhabiting the ocean floor, such as annelids, echiurid worms (*Echiurus echiurus*), and others. Small snails and mussels less than a millimeter in size have also been found in hagfishes, as well as the remains of shrimp and hermit crabs. Very active crabs almost certainly are consumed only after they have been injured. See also **Hagfishes (Agnatha)**.

The North Atlantic hagfish or common hagfish (*Myxine glutinosa*) lives on soft ground. Boring into the floor is accomplished by powerful swimming motions of the rear body portion in a vertical position. The bored-in passages are not coated with mucous, as is the case of some boring fishes.

Lampreys (subclass Petromyzontia). These fishes are also eel-shaped, but as adults they have well-developed eyes. The nasal orifice on top of the head has a blind end. There are 7 gill openings and a circular sucking mouth well supplied with teeth is on the lower side of the head. Lampreys lack barbels. They have 2 dorsal fins and 1 caudal fin. Lampreys are free-living inhabitants of salt and fresh water.

Lampreys undergo metamorphosis similar to amphibians and some fishes; they have a juvenile stage, which as a larva is structured differently from the adult form and leads a completely different way of life. In many cases, the larvae even inhabit another environment. Two groups can be differentiated: (1) Migrating forms and, (2) freshwater forms. Members of the former group live as adults in the ocean or in brackish water near the coast, but after a period of time migrate into rivers and streams, where they lay their eggs and where their larvae live until they metamorphose. After metamorphosis, the young larvae migrate again to the coast. Species of the second group spend their lives in fresh water and do not migrate. See also **Lampreys (Agnatha)**.

As a result of filter feeding, the growth of lamprey larvae proceeds slowly. The larvae reach a length of less than 1 inch (about 2 centimeters) after 1 year. After 4 to 5 years, the larvae are 4 to 8 inches (10 to 20 centimeters) long.

Well known among the lampreys is the American sea lamprey (*Petromyzon marinus dorsatus*), which has been greatly responsible for reducing the whitefish population in the Great Lakes. See also **Whitefishes**.

CYCLOSTROPHIC WIND. See **Winds and Air Movement**.

CYCLOTRON. A device for accelerating charged particles to high energies by giving particles traveling in a spiral path successive increments of energy from an alternating electric field between electrodes placed in a constant magnetic field. The path radius increases as energy increases.

CYGNUS (the swan). One of the most striking and interesting constellations of the northern sky, also frequently referred to as the northern cross. Cygnus represents a swan flying with outstretched wings, and legs trailing out behind. Lying, as it does, in one of the most impressive portions of the northern Milky Way, the constellation contains many interesting objects. Its brightest star (α Cygni), known as Deneb, has an intrinsic brightness about 1,000 times that of the sun, and is among the most distant of all of the bright stars. One of the most striking of all of the double stars is β Cygni, whose two bright components, one blue and the other orange, may be easily separated by a small telescope. This star is probably not a true binary, since no physical connection has been determined between the components. Another interesting member of Cygnus is the relatively faint star noted as number 61 on large star maps, the first star to be measured for its distance from the earth. The astronomer Bessel's determination, in 1838, of the stellar parallax of this object opened a field of astronomical research that has done much to solve many problems of general cosmogony. See map accompanying entry on **Constellations**; also **Black Hole**; **Radio Astronomy**; and **X-Ray Astronomy**.

CYLINDER (Geometry). A solid bounded by a cylindrical surface and two parallel planes. The terms cylinder and cylindrical surface are often used interchangeably but, as stated, the former is a solid and the latter a surface.

$$\text{Area FGK} = \text{Area FMGK} - \text{FMG}$$

$$\text{Area FMGK} = \left(\frac{2\angle\text{FMD}}{360}\right) \times \text{Area of Circle.}$$

$\angle$FMD is determined from its cosine.

$$\text{Volume of Tank} = \text{Area FGK} \times \text{Length (same units)}$$

The two plane surfaces bounding a cylinder are its bases, and the cylindrical surface is its lateral surface. The altitude of a cylinder is the perpendicular distance between its bases. If the elements of a cylinder are perpendicular to its bases, the cylinder is called a right cylinder; otherwise, it is oblique. If the bases are circles, it is a circular cylinder. A cylinder of revolution may be generated by rotating a rectangle about one side as an axis, and the result is a right circular cylinder.

The following relations refer to a cylinder of revolution: $S = Ch = 2\pi rh$; $A = 2\pi r(r + h)$; $V = \pi r^2 h$, where the symbols mean: S, lateral area; C, r, circumference and radius of lower base; h, altitude; A, total area; V, volume. For any cylinder, $V = bh$, where b is the area of the base.

Because it is comparatively easy to form, by usual means of manufacture, and because its shape is very well adapted to the resisting of internal bursting pressure, the cylinder is a very common engineering shape. While, of course, anything of cylindrical shape might truly be called a cylinder, it is customary to apply the term to that part which, in conjunction with a closely fitting internal piston will provide an enclosed space the volume of which may be varied by motion of the piston. Expansion of volume of a working medium is the basis of all commercially employed power cycles, and the cylinder and piston have an important place in this field.

Tanks in the form of cylinders also are widely used for storing liquids and gases, while cylindrically shaped silos are used for storing a variety of bulk solid materials, such as grain and chemical raw materials. Tanks may be erected vertically or horizontally. Calculation of the volume of contents in vertical tanks for various levels simply requires use of the aforementioned formulas. See Fig. 1.

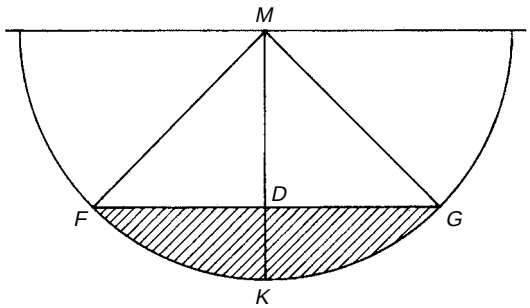

Fig. 1. Volume calculations of cylindrical tanks.

CYLINDRICAL COORDINATE. A curvilinear coordinate system of right-circular cylindrical surfaces forming families of circles about the origin in the XY-plane of a rectangular Cartesian system ($\rho = \text{const.}$); half-plane from the Z-axis ($\phi = \text{const.}$); planes parallel to the XY-plane ($z = \text{const.}$). The position of a point in this system is given by (ρ, ϕ, z) where $x = \rho\cos\phi$, $y = \rho\sin\phi$, $z = z$. See Fig. 1.

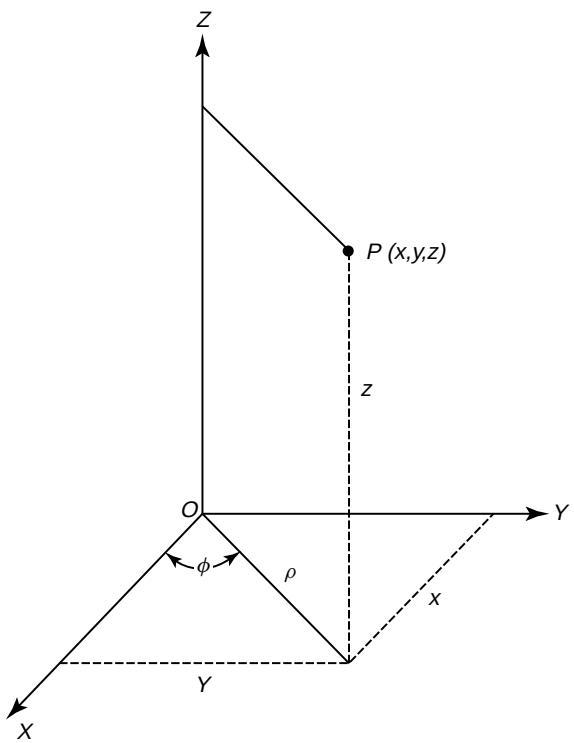

Fig. 1. Cylindrical coordinate system.

More precisely, the system should be called circular cylindrical because elliptic and parabolic cylindrical coordinates also exist.

See also **Coordinate System**.

CYPRESS TREES. The term cypress is not scientifically specific, but as will be noted from the following list of cypress trees, cypresses are found in two families and in various genera, only a few of which are in the genus Cupressus (true cypresses). The two families represented are: (1) Cupressaceae (cypress family); and (2) Taxodiaceae (swamp cypress family). In addition to Cupressus under Cupressaceae, there is the genus Chamaecyparis (false cypresses). A further complication is the fact that several cypresses are called cedars in the commercial world. Thus, some of the cypresses listed below, as noted, are described in the entry on **Cedar Trees**.

It is interesting to note that in addition to the cypress trees just listed, other genera of *Cupressaceae* (cypress family) include the thujas

or arborvitae, the incense cedars, and the junipers; and other genera of *Taxodiaceae* (swamp cypress family) include the dawn redwoods, the giant sequoias, coast redwoods, and a small group known as Pacific cedars. See also **Giant Sequoia**; and **Redwood (Coast)**.

The True Cypresses

Probably the best known of the true cypresses is the classic or Mediterranean or Italian cypress, highly regarded for its decor and use in formal landscaping. The tree does very well in the Mediterranean region. It is also found in other parts of the world where it has been introduced and does well provided that climate and soil conditions are appropriate. It is found in the southern United States and along the southern part of the West Coast. In northern areas where the classical cypress cannot be used, the Lombardy poplar provides somewhat the same landscaping effect. The classical cypress can attain a height of from 50 to close to 100 feet (15 to 30 meters) and retains its stately, formal and rather narrow columnar shape with a top that resembles a huge rounded pencil point. Of an entirely different contour and skeletal form is the Monterey cypress, which thrives right at the edge of the Pacific Ocean along the California coast. It has a rather ancient, windswept appearance, often with proportionately little foliage for its size. However, when protected from high winds and heavy weather, the tree takes on a different appearance, but it is always characterized by multiple stems. When grown in a garden, the tree appears something like a bushy cedar of Lebanon. The Monterey cypress has been introduced into New Zealand in connection with reforestation. The Kashmir cypress, which is of a blue-green color, attains a maximum height of about 20 feet (6 meters) and is of a weeping contour. It is a difficult tree to raise and hence is quite rare. The Arizona smooth cypress is found in the southwestern United States and hence is well-named. It is pyramidal in shape, somewhat columnar, but not nearly so formal as the classical cypress. The foliage is bluish-gray, with thick upswept branches. True cypresses of the Southern hemisphere include the Australian *Callitris* and the Chillean *Fitzroya*. The latter is quite a large tree, native to the Andes. Specimens introduced into favorable and comparable climates in the Northern Hemisphere have done quite well. The Mexican cypress (or cedar of Goa) is the only true cypress that is referred to as a cedar. The tree was named after Lusitania (Portugal). See Fig. 1.

Fig. 1. Group of broad-topped Monterey cypress trees in California. (*Photo by A Gaskill.*)

Italian cypress	See Classic cypress
Japanese Sawara cypress	*Chamaecyparis obtusa* (A false cypress)
Kashmir cypress	*Cupressus cashmeriana* (A true cypress)
Lawson cypress	*Chamaecyparis lawsonia* (A false cypress, but better known as Port Orford cedar. See entry on **Cedar Trees**.)
Leyland cypress	*Cupressocyparis leylandii* (Closely related to the false cypresses, but of a separate genus known as the Leyland cypresses.)
Mediterranean cypress	See Classic cypress
Mexican cypress (or Montezuma cypress)	*Taxodium mucronatum* (A swamp cypress)
Mexican cypress (or Cedar of Goa)	*Cupressus lusitanica* (A true cypress, but known as the Cedar of Goa. See entry on **Cedar Trees**.)
Monterey cypress	*Cupressus macrocarpa* (A true cypress)
Nootka cypress	*Chamaecyparis nootkatensis* (A false Cypress, but better known as the Alaska Cedar. See entry on **Cedar Trees**.)
Pond cypress	*Taxodium ascendens* (A swamp cypress)
Santa Cruz cypress	*Cupressus abramsiana* (A true cypress)
Smooth Arizona cypress	See Arizona smooth cypress
Southern cypress	See Bald cypress
Swamp cypress	See Bald cypress
White cypress	*Chamaecyparis thyoides* (A false cypress, but better known as the Atlantic white cedar. See entry on **Cedar Trees**.)
Yellow cypress	See Nootka cypress

False Cypresses

Important species include the Lawson, Nootka, and white cypresses, commonly referred to as cedars, and discussed under **Cedar Trees**. The Leyland cypress is a hybrid of the Nootka cypress and the Monterey cypress, and was first developed in Wales about 1925. Since then, the tree has become highly regarded in Britain as an excellent garden tree. The tree is hardy, shapely, dense with foliage and of good color. It is also prized for its fast rate of growth. A 30-foot (9-meter) specimen may be obtained in about 10 years, and is considered capable of attaining a height of about 100 feet (30 meters). The tree usually reaches a height of about 6 feet (1.8 meters) in its first 3 years. The flame-like shape is retained as the tree grows tall.

Swamp Cypresses

The bald cypress is found in the United States from Delaware to Florida and westward through the Mississippi valley and in some midwestern states. The tree is well-named because it prefers swampy environments. It frequently is found standing in water. The height ranges from 80 to 120 feet (24 to 36 meters). Parts of the tree rise out of the water like knees, measuring from 8 to 30 inches (20.3 to 76.2 centimeters) in height. The tree does not develop these knees unless it is growing in a watered area. Roots extend downward from the knees, providing the tree with adequate anchoring when it rises from a muddy, soggy base. The knees per se make interesting souvenirs, as well as providing a material from which to make interesting artistic objects. The knees sometimes are used effectively in flower arrangements. See Fig. 2.

The bark of the bald cypress is heavy, thick, pale-brown and its broad ridges have a vertical pattern. The branches of the tree are slender; the tips have thick scales. The cone is small, about $1\frac{1}{2}$ inches (3.8 centimeters) in diameter. The wood of the bald cypress is somewhat heavier than white pine, is straight-grained and easily worked. The wood is used in general construction and as an interior finish wood.

The champion cypress trees in the United States as selected by The American Forestry Association are listed in Table 1.

For references, see also **Tree**.

TABLE 1. RECORD CYPRESS TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Arizona smooth cypress (1998) *(Cupressus arizonica var. glabra)*	196	498	70	21.3	40	12.2	Arizona
Arizona cypress (typ.) (1993) *(Cupressus arizonica var. arizonica)*	240	610	93	28.3	48	14.6	Arizona
Blue cypress (1994) *(Callitris hugelii)*	180	457	60	18.3	58	17.7	Florida
Gowen cypress (typ.) (1999) *(Cupressus goveniana var. gaveniana)*	66	168	40	12.2	52	15.8	California
Mendocino cypress (1991) *(Cupressus goveniana var. pigmaea)*	267	678	142	43.3	40	12.2	California
Monterey cypress (1999) *(Cupressus arizonica var. nevadensis)*	537	1360	102	31.1	116	35.4	California
Piute cypress (1976) *(Cupressus arizonica var. nevadensis)*	124	315	32	9.75	40	12.2	California
Sargent cypress (1991) *(Cupressus sargentii)*	148	376	145	44.2	40	12.2	California
SWAMP CYPRESS							
Montezuma bald cypress (1995) *(Taxodium mucronaium)*	268	681	85	25.9	87	26.5	Texas
Pond cypress (1999) *(Taxodium distichum var. nutans)*	243	617	115	35.1	54	16.5	Georgia

CYPRINIFORMES. See **Carp**; **Bitterling**; and **Fishes**.

CYST. 1. A capsule containing semisolid or fluid material which may be under pressure. The contents of a cyst may be retained normal secretions, e.g., the sebaceous cyst which contains the products of a plugged sebaceous gland; or they may represent a fluid collection associated with a parasitic infection, e.g., echinococcus cysts of the brain, liver or other organs. Many tumors undergo cystic degeneration, especially carcinomas of the ovary, breast, and uterus. Benign cysts occur in the ovary, spleen, lungs, kidney and liver where they are often congenital. Other congenital cysts result from fetal malformations and failures of development, such as the several cysts that occur in the neck. 2. The resting form of an organism in a protective covering. Significant examples in medicine are the cysts of *Endamoeba histolytica*, which are found in the stools of patients with amebiasis, and the encysted larvae of *Trichinella spiralis*, which can be demonstrated in the muscles of individuals who have had trichinosis.

CYSTIC FIBROSIS. An inherited debilitating and ultimately fatal disorder that includes chronic lung disease and pancreatic insufficiency. With the improved care developed for cystic fibrosis (CF) patients over the past decade, the median survival age has risen from the early 20s to the present median of 25 years of age. It no longer is rare to find a few patients that reach an age in the early 30s.

Although the gene for CF was located in 1989, this new information has not led, to date, to any form of genetic therapy that once was envisioned. Most professionals are of the opinion that genetic therapy, if possible, lies well into the future. However, the genetic research has and continues to increase the knowledge base, which in the short term can further improve therapeutic intervention and, by way of screening, lead to fewer births of individuals who would be at high risk of inheriting the faulty CF gene.

In a July 1990 report,[1] it is estimated that CF affects approximately 1 in 2500 persons of European ancestry. It is less frequent among black and Hispanic Americans and is rare in Asians. One in 25 persons of European ancestry is a carrier having one normal and one CF gene. Where the father and mother each carry the defective gene, there is a 1 in 4 risk with each pregnancy that the child will have the CF gene. Two copies of the gene must be passed on, one from each parent, if the child is to inherit the disease.

Because CF involves a number of complex processes, some of which still remain poorly understood, CF is difficult to describe in simple terms. It is particularly difficult to differentiate the two main components of the disease (i.e., the *lung involvement* and the *pancreatic insufficiency*). Both of these interrelated components derive from the CF gene, which, through a complex process, causes the production of abnormal mucus. This thick, tenacious mucus secreted in the bronchi obstructs airways and impairs local defense mechanisms. In turn, this leads to persistent bronchial infection and accompanying inflammation. Among the causative bacteria, *Pseudomonas aeurginosa* appears to predominate in most CF patients. This infection, once established in the lungs, does not clear. Traditionally, CF patients

[1] Workshop on Population Screening for the Cystic Fibrosis Gene, National Institutes of Health, Bethesda, Maryland. Published in the *N. Eng. J. Med.* (July 5, 1990).

have been treated much as a patient with severe and diffuse bronchiectasis would be. However, with CF patients there is no normal recovery because the mucosecretory process continues to create a favorable environment for the bacteria. In terms of understanding what might be called the second component, pancreatic insufficiency, researchers agree that they still have many more facts to collect.

Presently, intense research is being targeted on the electrophysiological aspects of the upper airway in cystic fibrosis. It has been established that the upper airway in CF is dominated by an increased sodium reabsorption, which, when combined with decreased chloride secretion, reduces the water content of airway secretions, thus making them more viscid and difficult to clear.

Location of the CF Gene

After 2 years of intensive research by several research teams, one team (Hospital for Sick Children [Toronto] and the Howard Hughes Medical Institute [University of Michigan]) located and described the CF gene. Earlier, in 1987, researchers at St. Mary's Hospital Medical School (London) had found a candidate gene, which proved to be a close neighbor of the CF gene.

Finding the CF gene (technically called the Cystic Fibrosis Transmembrane Conductance Regulator [CFTR] and which consists of 1480 amino acids) has since introduced additional complications, namely the finding of numerous mutants. At least 40 CF-causing mutations have been found.

Therapeutic Intervention

The principal targets for improving CF therapy by conventional methodologies include:

1. More efficient removal of the viscid secretions that interfere with lung action;
2. Careful management of the diet, including pancreatic enzyme supplements; and
3. Promptly controlling pulmonary infections through the use of advanced antibiotics and other medications.

Screening Programs

These programs can be effective in preventing the incidence of CF by counseling young parents in their family planning, particularly if there is a history of CF in one of the couples' families. As a start, a registry of some 16,000 CF patients is maintained by the Cystic Fibrosis Foundation. Researchers are concentrating on developing improved tests for identifying the CF gene and its mutants. As reported by Waters, et al., neonatal screening for CF with the use of the immunoreactive-trypsin assay on dried blood samples has been adopted by many medical centers worldwide.

Screening, particularly mass population programs, immediately precipitates sociological dimensions. These aspects are well covered by the "Workshop on Population Screening for the Cystic Fibrosis Gene" in the NIH reference listed.

CYSTINE. See **Amino Acids**.

CYTOCHROMES. The cytochrome *c*-cytochrome oxidase system represents the terminal segment of the respiratory chain common to the vast majority of organisms utilizing oxygen as the terminal oxidant in tissue respiration. The complete respiratory chain consists of a number of electron carriers, both protein and nonprotein in nature, organized in a definite sequence within the walls and internal partitions of subcellular organelles known as mitochondria. These structures carry the electrons that come from the substrates being oxidized and eventually react with oxygen. The energy released in several of the many steps of this series of reactions is utilized to make the high-energy compound adenosine triphosphate, a process known as *oxidative phosphorylation*. The high-energy compound is, in turn, employed to drive the many reactions of metabolism which require chemical energy. Every component of the terminal respiratory chain is reduced by the component immediately proceeding it and then reduces the component immediately following it in the chain, itself becoming reoxidized. The *c*-cytochrome oxidase system is common to all vertebrates and invertebrates, plants, as well as numerous microorganisms, and must be distinguished from systems having similar functions, but very different properties, which occur in numerous bacteria.

The cytochromes were first observed by MacMunn as early as 1886. He described their spectral absorption bands in a large variety of organisms and tissues. His discovery was, however, forgotten after a controversy with Hoppe-Seyler had raised doubts as to the validity of some of his conclusions, and it was not until 1925 that Keilin independently rediscovered the remarkable cytochrome spectrum in the flight muscles of a living insect.

Keilin's observations came at a time when the understanding of tissue respiration had advanced to the point of providing the foundations necessary for the unraveling of the physiological role and chemical nature of cytochromes. The first step had indeed been taken some 40 years earlier by Ehrlich when he found that a variety of animal tissues could transform a mixture of α-napththol and dimethyl-*p*-phenylenediamine to indophenol, in the presence of oxygen. A decade later, the enzyme responsible for this effect had been named indophenol oxidase, and it was shown that its activity was inhibited by cyanide. In the first decades of the twentieth century, Warburg, from studies of the catalysis of the oxidation of cysteine by iron-charcoal, considered a "model" of cellular respiration. He concluded that oxygen activation was the all-important process in cellular respiration and that an iron-containing enzyme, the "respiratory enzyme" or *Atmungsferment*, is solely responsible for the transport of the oxidizing equivalents of oxygen to the substrates. An opposing view was taken by Thunberg, who had detected a large variety of dehydrogenases in tissues, and by Wieland, who used palladium-hydrogen as a "model" of tissue respiration and believed that substrate-specific hydrogen activations were characteristic of all biological oxidation processes, the reaction with oxygen being nonspecific and relatively unimportant.

The controversy as to the respective roles and importance of hydrogen and oxygen activation faded into the background when, following his initial observations, Keilin demonstrated that the four-banded spectrum of cytochrome, observed in a large variety of tissues and organisms, was in fact the spectrum of the ferrous, or reduced, forms of three distinct cytochromes — cytochrome *a*, cytochrome *b* and cytochrome *c*. Keilin obtained a soluble preparation of cytochrome *c* from baker's yeast, and together with Hartree, in 1938–1939, showed that the indophenol

oxidase activity of particulate tissue preparations was simply the result of a nonenzymic reduction of cytochrome *c* by dimethyl-*p*-phenylenediamine, the reduced heme protein being oxidized by indophenol oxidase in the presence of oxygen. Having established the nature of the final steps of tissue respiration, they renamed the enzyme "cytochrome oxidase," since its only function appeared to be the oxidation of cytochrome *c*. There had been no doubt of the overwhelming physiological importance of the system ever since 1934, when Haas found that, in a number of tissues, the rate of oxygen uptake was identical to that of cytochrome *c* reduction, demonstrating that nearly all of the oxidizing equivalents of oxygen were transmitted by the cytochrome *c*-cytochrome oxidase system.

That the material in tissues reacting directly with oxygen was in fact a heme compound had been shown by the experiments of Warburg and collaborators on the effect of carbon monoxide on tissue respiration, carried out in the late 1920s. Warburg observed that carbon monoxide inhibits the uptake of oxygen by tissues and that this inhibition is reversed in bright light. Using this phenomenon, he succeeded in measuring the absorption spectrum of the carbon monoxide complex of the respiratory enzyme, a spectrum that turned out to be clearly that of a heme compound. Thus, when Keilin and Hartree in 1939 found that in the presence of carbon monoxide, cytochrome *a* showed up as two spectroscopic components, they were able to demonstrate that the new cytochrome, cytochrome a_3, was the substance responsible for the photochemical action spectrum of Warburg. Cytochrome a_3 was thus identified with the respiratory enzyme reacting directly with oxygen, and the system was considered to be composed of three entities, cytochromes *c*, *a*, and a_3, reacting consecutively, like all the other components of the respiratory chain.

Cytochrome *c* consists of a polypeptide chain, from 104 to 108 amino acid residues in length. A single heme prosthetic group is attached by thioether bonds formed between the sulfhydryl side chains of two cysteine residues in the protein and the vinyl side chains of the porphyrin ring as shown by

CYTOGENIC GLAND. An organ that produces and discharges cells, such as the reproductive glands.

CYTOKINES. Cytokines are "messenger proteins," soluble mediators that allow communication between cells. Together with hormones and neurotransmitters, they contribute to a chemicalsignaling language that controls development, tissue repair, inflammation and the immune response in multicellular animals.

Introduction

Cytokines can best be defined as small proteins (approx. 8–80 kDa (a unit of mass, being 1,000 daltons.) that usually act in an autocrine (on the cell that produced them) or paracrine (on cells close by) manner. The production of these potent molecules is usually transient and tightly regulated. After binding to specific cell surface receptors at the cell membrane, cytokines initiate a cascade that leads to induction, enhancement or inhibition of a number of cytokine-regulated genes, and ultimately, to altered cellbehavior.

Cytokines have a wide variety of names. This is not surprising as they have been discovered in disciplines ranging from immunology, virology and hematology to cell biology and oncology. Interleukins, interferons, colony-stimulating factors, tumor necrosis factors, growth factors, chemokines (chemotactic cytokines) and many other proteins with the word "factor" in their name, can all be considered cytokines.

Cytokines can have multiple functions. Indeed, it is not unusual for a cytokine tobe isolated independently in several laboratories working with entirely different experimental systems. Another complication in studying these molecules is that they are rarely produced on their own and rarely act alone. There is also a great deal of functional redundancy with several cytokines sharing similar actions. Cytokines function in a complex network where production of one cytokine will influence production of, or response to, several others. In the past 5 years this array of 200+ effector molecules and associated cell surface receptors has been simplified by study of three-dimensional cytokine and cytokine receptor structure; elucidation of convergent intracellular signaling pathways; and molecular genetics, especially targeted gene disruption to "knock out" production of individual cytokines in mice.

The Major Cytokines and Their Receptors

Although there is little similarity between most of the individual cytokines or cytokine groups in terms of DNA or amino acid sequence, there are a few large families of closely related cytokines, most notably the alpha interferons (IFNα), with at least 15 functional members, and the chemokines, with more than 50 different mediators being predicted from genomic analysis. However, it is easy to divide the cytokines and their receptors into groups when three-dimensional protein structure is considered. See also **Interferons**.

The Cytokine Superfamily

The largest family of cytokines and receptors is called the cytokine or hematopoietic superfamily. Each different cytokine protein has a similar four-helix bundle motif and each receptor has a single transmembrane segment with its N-terminus outside and C-terminus inside. The extracellular portion of the receptor contains at least one homology region consisting of two fibronectin type III molecules. The intracellular regions, in contrast, are quite diverse. The cytokine–receptor complexes of this family (e.g. interleukin 2 (IL-2), IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13 and IL-15, granulocyte colony-stimulating factor and granulocyte–macrophage stimulating factor) modulate a wide variety of immune and inflammatory responses. Other members of the familyact outside the immune system (e.g. prolactin and erythropoietin). Receptors for the antiviral interferons (IFNs) as well as IL-1, IL-10 and macrophage colony-stimulating factor are also distantly related to this receptor superfamily. See also **Interleukins**.

Although most cytokine receptors have a single transmembrane domain, the actual functional receptor often consists of two or more subunits which can be shared among different cytokine–receptor complexes. A common pattern is for an individual cytokine to bind to a "private" and specific subunit and "public" subunits that are shared by other related cytokines. For instance, the receptor complex of the cytokine IL-2 consists of three subunits named α, β and γ. IL-2 Rβ is also used by IL-15 andIL-2 Rγ is also a subunit of the IL-4, IL-7 and IL-9 receptors. Similarly the IL-6

receptor has two subunits and β molecule (also known as gp130) is also used by cytokines such as leukemia inhibitory factor (LIF), oncostatin M and IL-11. The functional redundancy of certain cytokines may be partially explained by their common receptor subunits. For instance, IL-6, IL-11 and oncostatin M that share gp130, all act in a similar way on liver cells.

The Tumor Necrosis Factor Family

Another large family of cytokines and receptors are related to the tumor necrosis factors (TNFs). All cytokines of this family act as trimeric molecules and all bind to members of the TNF receptor family. Most of the ligands act as bound molecules but some ofthe receptors can have activity when secreted. Members of the TNF receptor family sharea ligand-binding domain composed of tandemly repeated cysteine-rich modules. Fifteen ligands and 22 receptors have already been identified and at least 20 ligands and 30 receptors are predicted on the basis of genome analysis. TNF family receptors can be roughly divided into "death domain" and TNF receptor-associated factor (TRAF)-binding receptors, although some can signal through both pathways depending on conditions. Death domain receptors activate intracellular proteases called caspases leading to apoptosis. The most potent apototic ligand so far discovered is TNF-related apoptosis-inducing ligand (TRAIL) which can bind to four different receptors and can kill susceptible cells within minutes ofexposure. Another well-characterized receptor that signals death is Fas. TRAF-binding receptors signal gene activation and these include nerve growth factor (NGF) and receptor activator of NF-*k* (RANK), which is involved in osteoclast activation. The ligand for RANK is ODAF (osteoclast activating and differentiation factor) and this regulatory system also includes OPG (osteoprotegerin), which is a secreted receptor for ODAF. OPG acts as a soluble "decoy" receptor blocking binding of ODAF to its cell surface receptor and thus inhibiting osteoclast formation. Another recently discovered ligand, a proliferation-inducing ligand (APRIL), is a potent stimulator of cell growth. Some members of theTNF family, particularly TNFα, are important in the regulation of immune and especially inflammatory responses.

The Chemokines

Chemokines are the largest mammalian cytokine family so far identified. They have distinct molecular structures and are unique among the cytokines in their chemotactic properties and ability to inhibit bone marrow progenitor cell growth. Compared with many other cytokines, chemokines are relatively small (7–10 kDa) comprising 70–80 amino acids. They are basic heparin-binding proteins that can be divided into two major groups named CXC (or α) chemokines and CC (or β) chemokines, according to the presence or absence of a single amino acid between two cysteine residues near the N-terminus, and sequence similarity. Chemokines bind to a distinct class of receptor called *seven transmembrane-domain receptors* because of their unique structure.

This large and functionally diverse superfamily is involved in neurotransmission, hormone action, and light perception as well as chemokine signaling. A few of the chemokine receptors are specific with only one chemokine known to bind, others are shared with several ligands. There is also one "promiscuous" receptor, known as the Duffy antigen. This is present on red blood cells and binds many different chemokines. Duffy antigen may be involved in "mopping-up" excess chemokine at sites of inflammation, hence containing and localizing these mediators. Some chemokine receptors, notably CCR3, CCR2b, CCR5 and CXCR4, act as cofactors for entry of human immunodeficiency virus (HIV) into macrophages and T cells. Individuals with a genetic polymorphism of the CCR5 gene, coding for a truncated receptor, appear to be resistant to sexual transmission of HIV.

Intracellular Signaling Pathways

Along with protein structure studies, research into signal transduction has unified cytokine biology. An increasingly well-defined chain of protein–protein recognition events tie the binding of a cytokine at the cell surface to the actions of diverse transcription factors inside the nucleus. The first step in cytokine signaling is ligand-induced dimerization of receptor components. The cytoplasmic regions of these receptor subunits interact to initiate a downstream signaling cascade. At its simplest, one receptor molecule may form a homodimer (two identical subunits) on ligand binding. Alternatively a "private" ligand binding receptor may then initiate hetero- or homodimerization of a"public" signal transducing domain.

JAK and STAT

All receptors of the cytokine receptor superfamily, along with receptors from some of the other cytokine receptor families, are associated with molecules called the *Janus kinases* (JAKs). Activation of cytokine receptors induces tyrosine phosphorylation and activation of JAK. JAK activation is required for most, if not all, receptor functions. Thus the primary function of the cytokine is to mediate receptor aggregation and the concomitant aggregation of JAKs. JAK kinases then couple ligand binding to tyrosine phosphorylation of various signaling proteins including the STATs (signal transducers and activators of transcription). STAT dimers translocate to the nucleus and bind directly to DNA.

The overlapping and yet unique functions of individual cytokines reflect the different intracellular signaling pathways involved. For instance, in T cells, the cytokines IL-2, IL-4 and IL-9 use the IL-2 Rγ chain and all activate JAK1 and JAK3; IL-10 activates JAK1 and Tyk2 and IL-12 activates JAK2 and Tyk2. The STATs have an even greater range of responses, with each cytokine activating a different set. They appear to be primarily involved in functional responses to cytokines. To add to the plasticity of signaling systems, it seems that the function of JAKs is not limited to the activation of STATs and that STATs can be activated by kinases other than JAKs.

MAP Kinases

Other signaling pathways, especially the Ras/MAP mitogen-activated protein kinase pathway, are involved in stimulation of cell proliferation by cytokines. Moreover, cytokines such as TNFα and IL-1β do not use the JAK–STAT pathway at all but activate members of the MAP kinase family (called ERK, JNK and p38) resulting in increased binding of the transcription factors AP-1, NF-*k*B and NFIL-6 to DNA.

TNF Receptor Signaling Pathways

The cytokines of the tumor necrosis factor family and their associated receptors can induce a number of different cellular interactions ranging from proliferation through differentiation to cell death. Apoptosis is induced via interaction with the receptor-associated signal transducer FADD (Fas-associated death domain; also called *mediator of receptor-induced cytotoxicity 1*, MORT1) and activation of a protease cascade. Gene activation and cell proliferation signals are mediated via the TNF receptor-associated TRAF (TNF receptor-associated factor) and TRADD (TNFR1-associated death domain) proteins. Ligands of the TNF family may also activate specific phospholipases such as the sphingomyelinases.

Chemokine Signaling

Engagement of the specific or shared chemokine receptors results ultimately in movement of the cell, but the intervening events involve signaling through receptor G proteins, mobilization of intracellular second messengers, reorganization of the cytoskeleton, formation of focal adhesions, attachment and detachment, pseudopodal extensions and retractions to give directional migration. Chemokines such as RANTES and MIP-1α (macrophage inflammatory protein 1) also activate STATs, implying crosstalk between G protein-mediated signaling and STAT-signaling pathways.

Cytokine Function

The signals resulting from cytokine binding ultimately lead to altered gene transcription, especially of molecules such as cellular adhesion molecules (CAMs), extracellularproteases, acute-phase proteins, lipid-metabolizing enzymes, nitric oxide synthase, othercytokines/receptors, major histocompatibility complex (MHC) molecules and, important to the antiviral actions of some cytokines, inhibitors of transcription. The resulting phenotypic changes can include proliferation, differentiation, growth inhibition, apoptosis, chemokinesis and adhesion to other cells.

The important role of cytokines in the body is amply illustrated by their action inthe immune response. In parallel with other signals arising from direct cell–cell or cell–antigen contact, cytokines provide a network controlling the intensity and length of the innate and specific immune response. They modulate inflammation, defense against virus infection,

proliferation of specific T and B cell clones, and regulate their differentiated function.

To give one example, the inflammatory cytokine response is primarily related to defense against bacterial infections. Endotoxin from Gram-negative bacteria and many other bacterial components or products (modulins) induce "pro-inflammatory" cytokines such asTNF α, IL-1, IL-6, IFNγ and IL-12. These cytokines then induce other cytokines especially chemokines, as well as prostanoids, leucotrienes and endothelial cell adhesion molecules. TNFα, IL-1 and IL-6 are also endogenous pyrogens and an increase in core body temperature may increase leucocyte activity. They also induce acute-phase proteins which opsonize the pathogenic organisms. Mobilization and extravasation of leucocytes from the lumen of the blood vessels to sites colonized by a pathogen is effected by localized cytokine-induced upregulation of endothelial adhesion molecules. Cytokine-induced chemokine gradients activate leucocyte adhesion molecules, causing slowing and rolling and ultimately diapedesis of leucocytes into the underlying tissues. Furthermore, cytokines produced by cells that have entered the inflammatory site will activate T and B cells, macrophages and fibroblasts. These in turn help determine the polarity of the T-cell response (see below) and stimulate hematopoiesis. The inflammatory response has an element of negative feedback and cytokines contribute to this. Cytokines that may downregulate include the IL-1 receptor antagonist, transforming growth factor β (TGFβ), IL-4and IL-10. See also **Lymphocytes**.

The immune response to infectious agents and other antigens is often polarized, with either a cell-mediated or antibody response predominating. It is now clear that local patterns of cytokine and hormone expression help to select the lymphocyte effector mechanism and that the polarized functional responses of CD4+ T helper (T_H) cells seem to be based on their profile of cytokine secretion. T_H1 cells produce the cytokines IL-2, IFNγ and TNFβ and favor cell-mediated immunity, delayed-type hypersensitivity, macrophage activation and production of opsonizing antibodies. T_H2 cells produce IL-4, IL-5, IL-6 and IL-10 and are associated with humoral responses, production of immunoglobulin E (IgE) and IgA and activation of eosinophils or basophils. The cytokine products of T_H1 and T_H2 cells are also mutually inhibitory for the functions of the reciprocal phenotype. The T_H1-T_H2 decision is crucial to effective immunity. It occurs early during an immune response and is influenced by many interrelated factors including the location of the immune response; the nature and concentration of the antigen; the antigen-presenting cells and the local cytokine microenvironment. Host genetic background may also play a role, as typifiedby the influence of TNF and IL-1 genetic polymorphisms on the pathophysiology of several inflammatory diseases. The cytokine IL-12, produced by macrophages and other antigen-presenting cells, is a potent initial stimulus for a T_H1 response. IL-12 induces T and natural killer (NK) cell IFNγ production within a few hours in both resting and activated NK and T cells. This IFNγ goes on to induce activation of phagocytic cells, chemokines and other cytokines, including more IL-12. The IL-12 and IFNγ also act on antigen-stimulated T cells, increasing their proliferation and differentiated function. In contrast, early production of IL-4 by T cell subsets and possibly basophils seems to be the most important cytokine in stimulating T_H2 cells.

Many CD8+ cytotoxic T cells make a spectrum of cytokines similar to T_H1 cells, whereas CD8+ cells that make T_H2-associated cytokines are associated with regulatory and suppressor functions. The differentiation of these cells may be affected by the CD4+ cell cytokine profile, with cytotoxic T cells commonly associated with T_H1 responses and less common when T_H2 cells are present.

Immune responses are not always strongly polarized in this way and it is possible that there will be other T_H subsets. However, T_H1 and T_H2 responses do play different protective roles and may contribute to immunopathology. Organ-specific immune disorders, acute allograft rejection and multiple sclerosis are typified by T_H1 responses and isolation of T_H1 T-cell clones. All T-cellclones from patients with atopic asthma caused by grass pollen have a T_H2 profile, as do cells from Crohn's disease and systemic lupus erythematosus.

Cytokine Networks

There are many cytokines with multiple functions and apparent redundancy of action. How can this complex network be unraveled and the *in vivo* role of individual cytokines be understood? Molecular genetics has proved a most powerful tool with the ability to genetically "knock out" a cytokine or its receptor in mice and has been another unifying force in cytokine research.

Molecular Genetics

Some cytokines, such as IL-7, TNFα and TNFβ (also called lymphotoxin) are important in the development of the immune system before birth. Mice deficient in TNFα have major defects in primary B cell function, impaired antibody follicles and marginal zones. The absence of others, e.g. IL-2, IL-4, IL-12 and IFNγ, is more obvious when animals are "stressed" by infection.

The importance of IL-12 in IFNγ production and normal delayed-type hypersensitivity responses has been demonstrated in deficient mice. Disruption of several cytokinegenes leads to intestinal lesions similar to those of human inflammatory bowel diseases, highlighting the fact that the tissue under the most constant antigenic pressure in the body is the bowel mucosa. The anti-inflammatory role of TGFβ is demonstrated by multifocal inflammation in deficient animals.

The importance of the IL-2 Rγ as a public signaling molecule used by a number of cytokines is demonstrated by the profound immune deficiency of mice lacking this receptor. All these results must be interpreted with some caution. The role of an individual cytokine in the mature animal, for instance, cannot properly be defined if its absence during development leads to a deficient immune system. However, it seems likely that amongst its redundant functions, an individual cytokine has one or more specific activities that have resulted in their conservation or even gene amplification during evolution.

Molecular genetic studies have also highlighted the role of cytokines in homeostasis of bone. Mice deficient for OPG, a secreted member of the TNF receptor family and an inhibitor of osteoclast formation, have a decrease in total bone density and a high incidence of fractures. Conversely, mice deficient in the ligand for OPG, ODAF, an osteoclast-activating factor, have severe osteopetrosis (thickening of the bone).

The functional importance of JAK and STAT can also be demonstrated in mice in whichthese genes have been deleted. For example, STAT1 deficient mice have quite specific defects in their responses to IFNα and IFNγ are exquisitely sensitive to virus infection; have defective macrophage nitric oxide production and show a T_H2 type response in infection. In contrast, homozygous deletion of JAK1 is lethal at the time of birth. Mice fail to nurse and are deficient in IL-7 signaling with a global inability to generate lymphocytes. Their phenotype resembles that of severe combined immunodeficiency (SCID) in humans.

Control of the Cytokine Network

The cytokine network is controlled *in vivo* in a number of ways. Individual cytokine production is transient and tightly, often spatially, regulated. Cytokines may induce or inhibit production of other cytokines and their receptors. They act synergistically or antagonistically, the response of an individual cell being determined by the cytokine context "seen" at its surface, and the stage of development of that cell. There is at least one example (in the IL-1 system) of a receptor antagonist that binds to a specific receptor but does not transmit a signal. Conversely there may be an IL-1 "deceptor" that specifically binds ligand but does not transmit a signal. Extracellular domains of cytokine receptors are shed and bind soluble cytokine molecules but it is not entirely clear whether they act as carriers or inhibitors of cytokine action. These soluble receptors may act to neutralize the cytokine but may also be carriers. For instance, a stablecomplex of IL-6 and its α receptor can signal cells that express the β gp130 receptor.

The level of cytokine production and magnitude of response may also be controlled at a genetic level. Particular alleles of genes such as TNFα and IL-1β, for instance, are associated with some inflammatory diseases, and this may be related to geneticdifferences in cytokine production.

There may be hierarchies in cytokine action with some cytokines having more scope of action than others, especially in terms of inducing other cytokines and their receptors. Such differences are suggestive of a cascade where only one or a few cytokines can initiate a network.

The cytokine network, with its antagonistic and synergistic actions, could possibly be considered as a signaling language where the individual cytokines are letters of an alphabet. A cell will "read" the message, as words or sentences made from the individual cytokine characters and their intracellular signals.

CYTOLOGY. A branch of biology dealing with the details of cell structure and studies of cell function. Cells may be examined in the living state by use of phase contrast microscopy (see Microscope) or with the conventional light microscope if "vital" stains are employed. These selectively stain specific structures in the living cell and render them more discernible. Alternatively, cells killed by chemical or physical fixation may have their components selectively stained for clarification of identity or function.

Knowledge of cytology has been greatly expanded through use of transmission and scanning electron microscopy, which have revealed internal and external details of cells too small to be seen with optical microscopes. An additional very powerful technique in cytology is the use of fluorescence microscopy, in which a specific cell substance such as protein or serum antibody is specifically conjugated with a fluorescent compound, thus rendering the cell substance uniquely visible when examined microscopically under, e.g., mercury lamp excitation.

CYTOTOXIC CHEMICALS. Chemical agents that damage cells to which they are applied. They are poisons, to which cells respond with injury, disease, or death. There are multitudes of cytotoxic chemicals; they act by a variety of mechanisms; and they have many different kinds of effects. See also **Carcinogens**.

A simplistic classification can start with biological alkylating agents of which a great variety exists. They all possess the ability to add alkyl groups to a wide range of electronegative groups under mild aqueous conditions. It is thought that some destroy growing cells by cross-linking the adjacent guanidine molecules on DNA. Others cause breaks in chromosomes while yet others uncouple oxidative phosphorylation, which leads to a loss of ADP and ATP and accumulation of AMP.

Antimetabolites are analogs of folic acid, the purines and the pyrimidines. In the first group, the effect is to block DNA synthesis by interfering with the deoxyuridylic acid → deoxythymidilic acid step. The second interferes with DNA synthesis by blocking conversion of inosinic acid to adenylsuccinic acid and xanthylic acid. Pyridimine analogs inhibit deoxythymidilic acid syntheses which results in failure of DNA synthesis and the death of proliferating cells.

Several antibiotics are also cytotoxic and combine with DNA, blocking its template activity in directing the synthesis of messenger RNA.

Many of these cytotoxic chemicals find application in treating various forms of cancer, but it must be remembered that they all also affect normal cells and their introduction to body organs can only be treated with great care and even apprehension.

D

DACITE. The name of a somewhat variable group of extrusive igneous rocks similar to the rhyolites but richer in plagioclase feldspar. Typical dacites are felsitic to porphyritic in texture. Dacites are the extrusive equivalents of the quartz-rich varieties of diorites and are sometimes classified as quartz-bearing andesites. The porphyritic types usually occur toward the center of the thicker dacite flows, dikes and sills, as well as the marginal zones of laccoliths. Dacites are common in the Cordilleran province of North, Central and South America. The term, dacite, was proposed by G. Stache of Austria for lavas in the old Roman province of Dacia.

DACRYOCYSTITIS. Infection of the lacrimal sac of the eye. The lacrimal glands produce tears for lubrication and protection of the eye. When the naso-lacrimal duct becomes obstructed, infection of the tear-producing sac is likely. Dacryocystitis appears most often in infants and in adults over 40 years of age. Secretions which cannot drain through the obstructed duct spill back out through the eye. Medical attention is required to avoid complications, such as infection of the cornea. See also **Vision and the Eye**.

DAGUERRE, JACQUES (1787–1851). Daguerre was a French inventor. Along with his partner, Charles Bouton, he developed the Diorama, which consisted of pictures painted on both sides of transparent linen. When lit they showed the front or back picture and made a visual effect for theater audiences. Later, he formed a partnership with Joseph-Nicephore Niepce to work on chemically fixing an image. Daguerre accidently discovered that mercury vapor would develop an image. He made a still life image in his studio.

He is credited with inventing the first successful and practical photographic process called "Daguerreotype". A daguerreotype was an individual positive picture with a reversed image. Many improvements in photography came quickly after his pioneering work.

See also **Photography and Imagery**.

J. M. I.

DALE, HENRY HALLETT (1875–1968). Henry Dale was an English physiologist and pharmacologist, whose work on chemical neurotransmission, especially by acetylcholine, elucidated a basic mechanism of nerve function. Born in London, Dale studied natural sciences at Trinity College, Cambridge and after a brief period in physiological research with John Langley, qualified in medicine from St Bartholomew's Hospital, London in 1902. He worked for Ernest Starling and William Bayliss at University College, before accepting a position in 1904 at the Wellcome Physiological Research Laboratories, which were associated with the pharmaceutical firm Burroughs, Wellcome and Co. Ten years later Dale joined the newly created Medical Research Committee (later Council) as head of the Department of Biochemistry and Pharmacology, at the National Institute for Medical Research (NIMR). Retaining his research commitments, he was also appointed first Director of the NIMR in 1928, and retired in 1942. See also **Bayliss, William Maddock (1860–1924)**; and **Starling, Ernest Henry (1866–1927)**.

His interests focused on the physiology and pharmacology of naturally occurring chemicals, and many different strands of his work began in the 10 years from 1904, when he was at the Wellcome Laboratories, and many fundamental observations and discoveries were made from experiments on a fungus, ergot of rye. Ergot was then used therapeutically to speed up labour, and it was because of these obstetric properties that Dale, and others at the time, were investigating its chemistry and pharmacology. His work started with the chance observation that an extract of ergot reversed the physiological effects of adrenaline in anaesthetized ferrets. Adrenaline had recently been shown to mimic the effects of the sympathetic nervous system, and Dale showed that the blood-pressure-raising effects of both sympathetic nerve stimulation, and the application of adrenaline were reversed by his extract, called ergotoxine. These were some of the earliest experiments that suggested mechanisms of chemical neurotransmission, and for this work Dale was later to share the Nobel Prize in Physiology or Medicine with Otto Loewi (in 1936). See also **Loewi, Otto (1873–1961)**.

In 1907 he discovered the chemical histamine in another extract of ergot, and with his chemical colleague George Barger determined its chemical structure and physiological actions. Histamine is found in most animal cells, and is released when the cell is injured, causing pain, redness and swelling. It is also found in wasp and bee stings, and stinging nettles, and accounts for their effects. Dale's work was of fundamental importance in understanding the role of histamine in both normal functioning and pathological conditions, and also provided the basic knowledge that later pharmacologists could use to develop antihistamine drugs. See also **Antihistamine**; and **Histamine**. In 1909 Dale made a further important discovery when he found that an extract from the posterior pituitary gland had oxytocic (uterus contracting) properties, which contributed to the elucidation of the physiological role of the gland and its secretions. The following year Dale and Barger, after an extensive chemical and physiological analysis of over 50 structurally related substances, introduced the useful term, 'sympathomimetic', now in general use, for chemicals that imitated the effects of the sympathetic nervous system. Further analyses of ergot, with the chemist Arthur Ewins, showed that it contained other physiologically active compounds, including a vasoactive substance, acetylcholine. Later work by Dale provided evidence that acetylcholine also occurred naturally in animals. Dale characterized its physiological effects, and described its action on smooth muscles, gland cells and the heart, all of which could be mimicked by the chemical muscarine; and effects that could be mimicked by nicotine on the cells of autonomic ganglia and the adrenal medulla. Later work revealed a similar nicotinic-like action at motor end-plates in the peripheral nervous system. This distinction allowed Dale, over twenty years later, to suggest and to establish, from experiments with several collaborators, most notably Wilhelm Feldberg, that acetylcholine had a precise physiological role at several sites in the autonomic nervous system and at the neuromuscular junction. In 1913 Dale made yet a further fundamental discovery, showing that anaphylactic contractions of smooth muscle resulted from the formation of cell-fixed antibodies, which changed the then prevailing views about the mechanisms of anaphylaxis, allergy and immunity. See also **Feldberg, Wilhelm Siegmund (1900–1993)**.

Closely associated with his research were his wider concerns, especially from the 1920s onwards, with the standardization of drugs, and he served on many advisory and regulatory committees at both national and international levels. In this direction he made enormous contributions to therapeutics throughout the world in establishing international standards for hormones, vitamins and various other drugs; he himself provided the first international standard for insulin. See also **Drug Discovery (The History)**.

D'ALEMBERT, JEAN-LE-ROND (1717–1783). D'Alembert was a French mathematician which published "d'Alembert's principle" which was a important new interpretation of Newton's Third Law. In his studies of physical astronomy, he solved the precession of the equinoxes. He also solved wave equation. He made important contributions to the field of algebra. He also wrote most of the mathematical and scientific articles for the monumental encyclopedia of his day.

See also **D'Alembert Principle**; and **Kinetics**.

J. M. I

D'ALEMBERT PRINCIPLE. The principle, first pointed out by d'Alembert in 1742, that Newton's third law (see also **Newton's Laws of Dynamics**) holds for forces acting upon bodies entirely free to move as well as upon fixed bodies in stationary equilibrium. In the former case the "reactions" concerned are due solely to inertia. Thus, in the act of throwing a ball, one pushes upon the ball with a certain force, and the inertia of the ball causes it to push back on the hand with an equal force. The condition of the system during such a process is said to be one of kinetic equilibrium. From this point of view, obviously, any system of bodies must always be in equilibrium, either kinetic or static.

DALTONIDE COMPOUNDS. See **Chemical Composition**.

DALTON, JOHN (1766–1844). Dalton was an English scientist who worked in the fields of biology, chemistry, earth science, mathematics, and physics. He became a professor of mathematics at the New College in Manchester, England. His beginning research work was on meteorology. Early in his career, he also studied color blindness. This was of special interest to him since Dalton was himself color-blind.

His teaching career required teaching chemistry and he began researching chemistry and meteorology and soon he proposed that in a mixture of gases, each component acts independently of the other gases present. This proposal is known as Dalton's Law. Continued research in this field led him to consider the nature of matter and he began to develop a systematic atomic theory based on quantitative chemical principles.

See also **Dalton Law**.

J. M. I

DALTON LAW. The law of partial pressures in mixed gases and vapors. If several gases not reacting chemically with each other are introduced into the same container, the pressure of the resulting mixture is equal to the sum of the pressures which would be observed if each gas were separately enclosed in that container. We may, for example, regard the atmospheric pressure as the sum of a nitrogen pressure, an oxygen pressure, an argon pressure, a carbon dioxide pressure, a water-vapor pressure, etc. The same principle holds for mixtures of the saturated vapors of two or more liquids evaporating in the same closed space, provided one liquid does not dissolve the vapor from the other (as water dissolves ammonia). Like other gas laws, this law is approximately valid only within limits. See also **Combustion**.

DAM. Dams are constructed for several purposes, including hydroelectric power generation, navigation, river control and flood prevention, irrigation, water system storage, with the creation of water playgrounds usually being an added dividend. Often, a single dam will serve several purposes. Increasing attention is being given to the total impact of a new dam on the topography and the numerous technical, sociological, and economic factors over the usually wide geographical region affected in some manner by the dam. Dams, over the years, have been constructed usually with one overriding purpose and, in some instances, have created unexpected impacts of an environmental and sociological nature, sometimes of a positive type: other times of a negative nature.

Like many other engineering achievements that have come under severe scrutiny by environmentalists, the building of dams must be studied carefully, but fairly, not overlooking the tremendous advancements and advantages that have resulted from the generation of low cost power, particularly important to developing nations, and the many thousands of lives that have been saved, not to mention billions of dollars of property damage, because of the effective use of dams in flood prevention projects. Dams also have served in numerous instances to improve upon nature in creating new ecosystems, which have contributed to the prevention and expansion of wildlife and natural recreational activities.

The characteristics of dams throughout the world in terms of height, volume, and reservoir capacity are listed in Table 1. Dams over 400 feet (152 meters) in height in the United States are listed in Table 2. See also **Hydroelectric Power**. There are scores of additional and what may be considered major dams throughout the world. Over 27 major dams have been built by the Tennessee Valley Authority on the Tennessee River system since 1933. In addition to their use for power generation, these dams make the main stream of the Tennessee River navigable over its 650-mile (1046-kilometer) length from Knoxville to the Ohio River. TVA provides electric power to over two million customers in parts of seven states, as well as large atomic and military installations.

Dam Classification and Construction

Dams may be classified as follows:

1. Timber dams.
2. Rock-fill dams.
3. Earth dams.
   - Plain.
   - Core wall.
   - Hydraulic fill.
4. Masonry dams.
   - Gravity, solid and hollow.
   - Arch, single and multiple.

Timber Dams. The timber dam is rarely used because of its short life and the limitation in height to which it may be carried. It is conceivable that in a location where timber is plentiful and cement costly and difficult to transport, and where only a submerged diversion dam is contemplated, the timber dam would be the most economical to construct, even taking due account of its lack of permanence.

Rock-Fill Dams. The rock-fill dam is an embankment of loose rock with either a water-tight upstream face of concrete slabs or timber, or a water-tight core. Where suitable rock is at hand in plentiful amount, a minimum of transport of materials can be realized with this type of dam. Like the earth embankment, it resists damage from earthquake shock very effectively.

Earth Dams. The earth dam, as shown in Fig. 1, is constructed as (a) a simple homogeneous embankment of well-compacted earth, (b) the same, but with a water-tight core or an upstream face pavement, (c) a hydraulic fill in which hydraulic segregation is relied upon to produce a water-tight core.

A major dam disaster occurred on June 5, 1976 in southeastern Idaho (44 miles; 71 kilometers north of Idaho Falls) when the earth-fill Teton Dam collapsed just as the water behind it was approaching full reservoir capacity for the first time. Downstream inundation caused 14 deaths and, at a minimum, about $400 million in property damage. The Teton Dam was considered multipurpose — planned to provide irrigation water, flood protection, electric power, and a water-sports recreational area. Site of the dam was in a deep, narrow canyon on the Teton River, which is in the watershed of the Snake River. Height of the dam was about 300 feet (91 meters) and the crest was about 3200 feet (975 meters) long. The reservoir extended some 17 miles (27 kilometers) up the canyon. Engineering of the dam was handled by the Bureau of Reclamation of the U.S. Department of the Interior, a bureau that previously had engineered about 250 earth-fill dams, all of which have performed satisfactorily.

Extensive studies were made of the collapse. The engineers were confronted with a number of unusual problems at the site. Rocks in the canyon walls and beds were highly fractured, thus providing many passages through which water could travel. Some fissures found during excavation of the dam foundation permitted easy passage for a person for up to about 100 feet (30 meters), but such passages did not converge with passages from the other side. Fissures are present at nearly every dam site to some extent and are not considered serious if they do not provide channels for water to reach the downstream face of the dam and thus cause erosion. Corrective measures were taken at the Teton Dam, including extensive cutting of trenches and pumping of grout in an attempt to create an impermeable barrier. Theoretically, the engineering measures taken were sound, but in practice did not suffice.

Major reasons given in the official report (see References) for failure of the dam were: (1) over-reliance on a grout curtain that turned out

TABLE 1. GREAT DAMS — HEIGHT/CAPACITY

to be imperfect; (2) use of "brittle" and "highly erodible" silts in the core of the dam and the trench fill; (3) selection of a poor geometrical configuration of the trenches; (4) inadequate provisions for collection and safe discharge of seepage or leakage; and (5) insufficient instrumentation to enable construction engineers to be aware of changing conditions in the dam embankment and the canyon walls. It is believed that the dam had probably been eroding for some time before visible signs of failure appeared just hours before the structure collapsed. Most investigatory reports concluded with the observation that the site was so poor that construction there never should have been seriously considered. The Teton Dam collapse initiated an extensive program for improving the inspection procedures for all large dams.

Masonry Dams. Masonry dams are of either the gravity or arch type. Stability is secured in the gravity dam by making it of such a shape and size that it will resist overturning, sliding and crushing at the toe. The dam will not overturn providing the resultant force falls within the base. However, to prevent tension at the upstream face and excessive compression at the downstream face, the dam cross section is usually designed so that the resultant falls within the middle-third at all elevations of the cross section. In the arch dam stability is obtained by a combination of arch and gravity action. If the upstream face is vertical the entire weight of the dam must be carried to the foundation by gravity, while the distribution of the normal hydrostatic pressure between vertical cantilever and arch action will depend upon the stiffness of the dam in a vertical and horizontal direction. When the upstream face is sloped the distribution is more complicated. The normal component of the weight of the arch ring may be taken by arch action, while the normal hydrostatic pressure will be distributed as explained above. Hence, for the gravity type, good impervious foundations are essential, but, for the arch type, firm, reliable support at the abutments (either buttress or canyon side wall) is more important. The most desirable site for an arch dam is a narrow canyon with steep side walls of sound rock. When situated on a suitable site, the gravity dam inspires more confidence in the layman than any other type. It has mass that lends an atmosphere of permanence, stability, and safety. When built upon a carefully explored foundation with stresses calculated from completely evaluated loads, the gravity dam probably represents the art of dam building at its highest point of development. This is an attribute of no mean significance because, due to flood disasters and their tremendous potentialities, fear of flood is a keenly developed human instinct. This factor has led to the adoption of the gravity section in some instances where an arch dam would have been the more economical construction.

Gravity dams are classified as *solid* or *hollow* (Fig. 2a and b). The solid type is the more widely used of the two, although the hollow dam is frequently the more economical to construct. Most forms of hollow dams have been patented by Ambursen and others. The gravity dams can also be classified as *overflow* and *non-overflow*. If the dam is to serve as a spillway section, its downstream face is ordinarily made an ogee curve with the curvature such that there will be no tendency of the water to leave the surface of the concrete, even with maximum water elevation at the crest.

Two types of single-arch dams (Fig. 2c) are in use: namely, the constant angle and the constant radius dam. The constant radius type employs the same face radius at all elevations of the dam, which means that as the channel grows narrower, as at the bottom, the central angle subtended by the face of the dam becomes smaller. In a constant angle type of dam, this subtended angle is kept a constant and the variation in distance from abutment to abutment at various levels taken care of by varying the radii. The safety of an arch dam is dependent on the strength of the side wall abutments, hence the arch should not only be well-seated on the side walls, but the character of the rock in bearing should be carefully inspected, to determine its ability to take the enormous thrust that will be set up as the water rises. The multiple-arch dam consists of a number of single-arch dams with concrete buttresses as the supporting abutments. The multiple-arch dam does not require as many buttresses as the hollow gravity type. It requires good rock foundation because the buttress loads are heavy.

Special Design Factors. In climates where ice may form on the reservoir surface, the ice expands upon a temperature rise and experts a force on the top of the dam. Conventionally, ice pressure factors of as great as 50,000 pounds per square foot (244,100 kilograms per square meter) have been used as a criterion in dam design for far-northern installations. More recently, Edwin Rose devised a method for calculating these forces, with resulting factors ranging from 2,000 to 10,000 pounds per square foot (9,764 to 48,820 kilograms per square meter). These depend upon the rate of temperature rise and the restraining conditions at the edges of the reservoir. Thus, the former values are now considered quite high from a practical standpoint.

Few areas of the world are free from earthquakes of varying intensity. Since earthquakes create both vertical and horizontal accelerations of

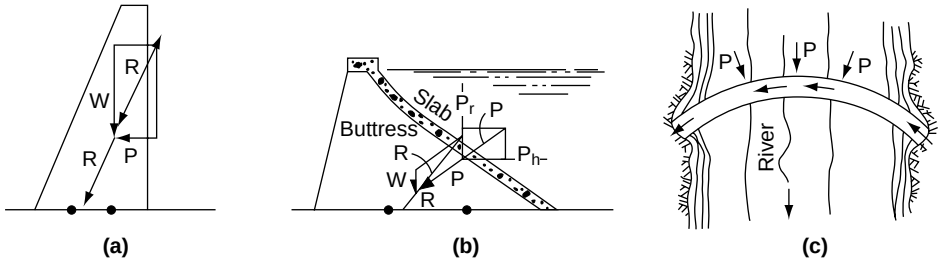

Fig. 2. Comparison of stabilizing forces in dams: (**a**) solid gravity dam. W is large enough, with respect to P, to incline R sufficiently to fall within the middle third. (**b**) hollow gravity dam. The slab is inclined enough to produce a vertical water pressure P, which inclines P sufficiently to overcome the effect of a small W, so that R falls within the middle third, (**c**) arch dam. Water pressure on the up-stream face has the effect of shortening the dam, thereby creating resisting compressive stresses within the dam and tightening it against the abutments.

any object resting upon the surface of the earth, a dam is vulnerable to earthquake damage — if not damage of a major nature, cracks and fissures may develop, the cost of repairing of which cab be extremely high, particularly if an important dam must be reduced in or taken completely out of service for a period. Of course, major damage to a dam that may result in collapse or extensive cracks and fissures can add flood damage to an already earthquake damaged region. In seismically active regions, dams have been designed for an acceleration equal to 0.1 g, where g is the acceleration due to gravity. A useful formula for approximating earthquake forces on a dam was developed in 1933 by von Karman:

$$F_e = 0.555\, awh^2$$

where F_e = inertial force of the water on the face of the dam
w = unit weight of water, pounds per cubic foot
a = acceleration due the earthquake, feet per second^2
h = depth of water behind dam, feet

DAMPING. With reference to industrial and scientific instruments, the Instrument Society of America defines damping as the progressive reduction or suppression of the oscillation of a system.

— When the time response to an abrupt stimulus is as fast as possible without overshoot, the response is said to be *critically damped*.
— *Underdamped* when overshoot occurs.
— *Overdamped* when response is slower than critical.

Relative Damping. For an underdamped system, a number expressing the quotient of the actual damping of a second-order linear system or element by its critical damping.

For any system whose transfer function includes a quadratic factor: $s^2 + 2z\omega_n s + \omega_n^2$ relative damping is the value z, since $z = 1$ for critical damping. Such a factor has a root $-\sigma + j\omega$ in the complex s-plane, from which $z = \sigma/\omega_n = \sigma/\sqrt{\sigma^2 + \omega^2}$

where s = complex variable
w_n = natural frequency, rad/second
z = damping ratio
σ = real part of the complex variable (s)
$j = \sqrt{-1}$
ω = frequency, rad/second

Damping Factor. For the free oscillation of a second-order linear system, a measure of damping, expressed (without sign) as the quotient of the greater by the lesser of a pair of consecutive swings of the output (in opposite directions) about an ultimate steady-state value. See Fig. 1.

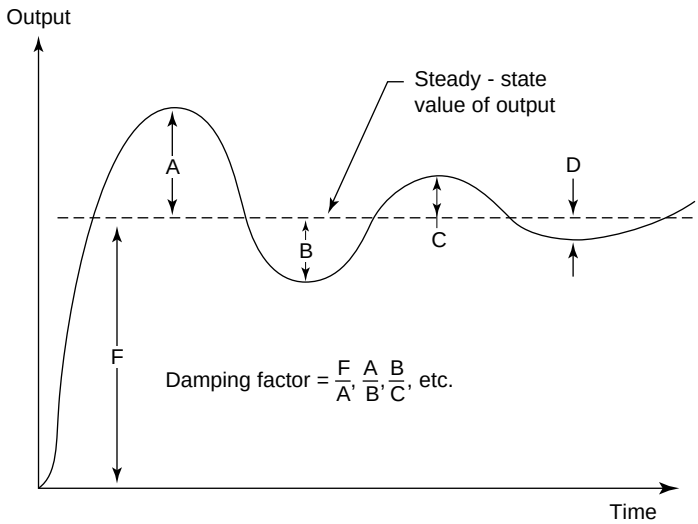

Fig. 1. Underdamped response of a system with second-order lag.

DANBURITE. The mineral danburite, $CaB_2Si_2O_8$, calcium-boron silicate, crystallizes in the orthorhombic system in prismatic forms somewhat

resembling the mineral topaz. Its fracture is subconchoidal; brittle; hardness, 7; specific gravity, 2.97–3.02; color, colorless, yellowish-white, yellow, dark wine yellow and brownish-yellow; luster, vitreous to greasy; translucent to transparent. It is found at Danbury, Connecticut, from whence its name was derived, Saint Lawrence County, New York, Switzerland, Japan, and Madagascar.

DANSGAARD-OESCHGER EVENTS. Warm–cold oscillations during the last glacial period recorded in the oxygen isotope record of the Greenland ice, and also found in biotic and isotopic indices from deep-sea sediments in the North Atlantic. The warm phases of these events correspond to interstadials, persist for a few hundred to a few thousand years, and have very rapid onset and termination (as little as a few decades). The range of temperature change inferred for the regions where the snow was formed that ultimately produced the Greenland ice was several degrees Celsius. Named for the ice core paleoclimatologists Willi Dansgaard and Hans Oeschger, Dansgaard–Oeschger events between 80 000 and 20 000 years ago are grouped in 10 000- to 15 000-year periods of increasing cooling. The ending of each of these groups of events is marked by a major flux of icebergs into the North Atlantic, as evidenced by associated material found in ocean floor sediments. The temperature conditions in Greenland and the North Atlantic region then return to the higher level of the beginning of the group of Dansgaard–Oeschger events. Most of the Dansgaard–Oeschger events that lasted 2000 years or more coincide with warmer conditions in East Antarctica, also revealed by analysis of oxygen isotopes in ice.

DARCY'S LAW. Darcy's law is a mathematical relationship originally determined by Henry Darcy in 1856 that permits quantification of fluid flow through porous media. Many sophisticated theoretical and practical derivations have been based on Darcy's law, and it has become the foundation for quantitative groundwater flow science and soil physics. In its most useful form, the formula can be used to calculate the amount of water (or other fluid) flowing through a given cross-sectional area of a porous substance and equates volumetric discharge per unit time (q) to the product of area (A), hydraulic gradient (I = change in head per unit length) and a coefficient (K = saturated hydraulic conductivity). In its simplest terms, the relationship may be expressed as $q = KIA$.

Figure 1 provides a schematic diagram for establishing the relationship in a laboratory soil column test for one-dimensional flow. Note that $\Delta h/L = I$. For a given porous media in a tube of cross-sectional area A, the hydraulic conductivity, K, can be determined as the only unknown in the equation. By changing the hydraulic head, it is also possible to confirm that the relationship between head and discharge is linear for most materials. It should also be possible to determine the head or discharge conditions for which the relationship deviates from the linear form and therefore the threshold beyond which Darcy's law is no longer applicable.

Since it was determined, Darcy's law has been found valid for any Newtonian fluid. It is important to note, however, that the relationship holds only for laminar (nonturbulent) flow of fluids in homogeneous porous media and that it was established under saturated flow conditions for one-dimensional flow. The Darcy equation is strictly applicable only when the cross section being considered is much greater than the dimensions of its microstructure, so that it can reasonably be regarded as uniform. Most groundwater movement takes place in small interstices, so that an aquifer provides considerable resistance to water movement, allowing laminar flow.

The determination of laminar flow depends upon the magnitude of the Reynold's number, a dimensionless ratio of inertial forces to viscous forces. At low Reynold's numbers, viscous forces dominate, and Darcy's law is valid. There follows a transition zone in which inertial forces become more important; Darcy's law cannot be accurately applied to the nonlinear laminar flow in this zone. Flow in the turbulent zone is both nonlinear and nonlaminar, and deviations from Darcy's Law can become very large. In many aquifer materials, however, the assumption of laminar water flow may not cause any inaccuracies.

Flow analysis predictions based upon Darcy's law in the presence of massively fissured rocks such as karstic limestones or highly fractured crystalline rocks can lead to large errors. Flow in such cases cannot be described adequately by a linear relationship such as Darcy's law, and a more detailed analysis is required. In very large interstices such as those found in many limestone and volcanic areas, groundwater flow is almost identical to the turbulent flow of surface water. Others have claimed that in clays that have very small pores and low hydraulic conductivities the very low flow rates are less than proportional to the hydraulic gradient. A possible explanation is that much of the water in such material is strongly held by absorptive forces and may be more rigid and less mobile than ordinary water. Similar processes may explain the large store of water held in peat soils that have very low hydraulic conductivities.

As Hofmann and Hofmann discuss, Darcy himself was careful not attribute too much to the specific magnitudes of individual data readings. Rather, he emphasized two aspects that his data supported, the proportionality of flow rate to total hydraulic head and the inverse proportionality of flow rate to column length. The limited experimental accuracy and scope were recognized by Darcy and have remained apparent to hydrologists ever since. By itself, Darcy's law suffices to describe only steady flow conditions, so that for most field applications it must be combined with mass conservation (or the continuity law) to obtain the general flow equation or, for saturated conditions, the Laplace equation. A direct solution of the latter for groundwater flow is generally not possible, and hence there is a need for various approximations or indirect methods of analysis. An important extension of Darcy's law to groundwater flow is its application in three-dimensions; see **Childs and Shaw** for more detail.

Fundamental to the application of Darcy's law is knowledge of the hydraulic conductivity of the saturated medium. The factors affecting hydraulic conductivity include those associated with the fluid and those associated with the aquifer, including temperature, salinity, pore space geometry, and soil or rock surface roughness. Hydraulic conductivity is often measured on a variety of scales ranging from a laboratory soil column, as shown in Fig. 1, to field-scale borehole tests and timed movement of tracers. As the scale of approach increases, often the estimation of hydraulic conductivity increases because of the incorporation

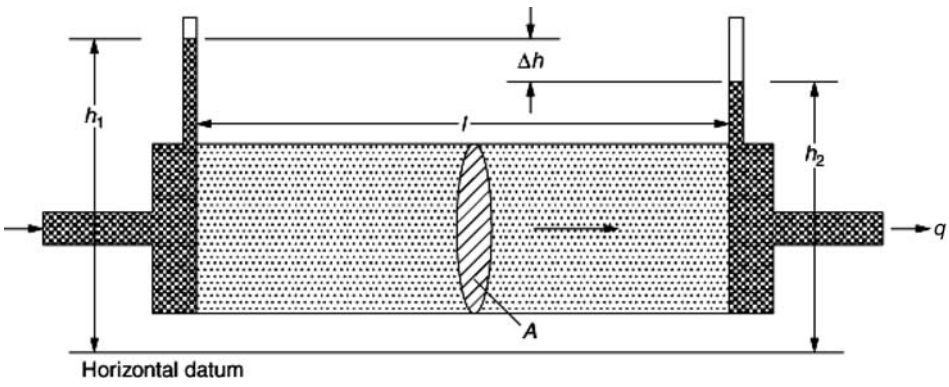

Fig. 1. Schematic diagram of a soil column test for establishing components of Darcy's law.

of ever larger and more extensive fracture systems. A practical difficulty is that virtually any matrix considered, even on the laboratory scale, will be heterogeneous to some extent. Such heterogeneities do not theoretically prohibit the use of Darcy's law, but they lend uncertainty to generalizations on a large scale. It is for this reason that statistical models employing probabilistic parameter distributions are sometimes used to model the spatial variability of hydraulic conductivity.

However, particular problems emerge in assessing spatial variability in hydraulic conductivity and applying Darcy's law to groundwater flow when media are anisotropic. This is the case for highly layered soils such as peats where hydraulic conductivity may differ in the vertical direction by several orders of magnitude across just a few centimeters. Furthermore, full saturation of soils may be prevented by gases occupying pore spaces after entrapment upon rapid infiltration or gas production as a result of biogenic decomposition. This can lead to a reduction of hydraulic conductivity. Many wetland soils are compressible and so the field worker must be careful not to misapply rigid soil theories to these soils. Instead, compressible soil calculations have been developed but are not yet widely applied.

Despite concern about its strict validity, Darcy's law constitutes an adequate description of groundwater flow and fluid flow through porous media. It can be successfully applied to virtually all normal cases of groundwater flow and is equally applicable to confined and unconfined conditions. See also **Groundwater Flow and Processes**.

DARK ADAPTATION. The process by which, the iris and retina of the eye adjust to allow maximum vision in dim illumination, following exposure of the eye to a relatively brighter illumination.

If the average luminance on the retina decreases suddenly from daytime photopic levels, a light source's just-detectable threshold luminance (alternatively, its threshold illuminance at the eye) decreases steadily for three to four minutes. This occurs because the eye's cones become much more sensitive during this period, although their sensitivity does not increase afterward. Note that cones are the only photoreceptors found in foveal (or central) vision, but that they coexist with rods outside the fovea. After about seven to ten minutes in very low-light scotopic conditions (0.1 lux or less), the rods become more sensitive than the cones, and visual sensitivity once again increases, reaching a maximum at about 20–30 minutes. The fully dark-adapted eye is nearly 10^5 times more sensitive than it is at daytime light levels, and the maximum rod sensitivity is about 10^3 times the maximum cone sensitivity. Although dark-adapted observers have a much lower threshold illuminance for detection, this is offset by the greatly increased threshold contrast in scotopic conditions. Mesopic vision occurs when both rods and cones contribute to vision at light levels between entirely photopic and scotopic conditions. Cones dominate photopic vision while only rods contribute to scotopic vision. Color vision is not possible in scotopic conditions, and the peak spectral sensitivity of scotopic vision occurs at shorter wavelengths than it does for photopic vision. Thus to the dark-adapted eye, blues and greens tend to look brighter than reds (the Purkinje shift).

DARK CURRENT. A current that flows in photoemissive and photoconductive detectors when there is no radiant flux incident upon the electrodes (total darkness). The dark current may vary considerably with temperature.

DARK-FIELD ILLUMINATION. For observing very small particles or very fine lines with a microscope, a condenser is used which sends the light through the object at such angles that it does not pass by transmission into the objective. Small particles or lines serve to diffract the light so that a small particle appears as a bright star against a dark background.

DARLINGTON PAIR. A particular transistor amplifier configuration using two transistors in cascade offering higher input impedance and greater gain stability than available from the conventional cascade connection of two common emitter stages. See accompanying diagram.

DARWIN, CHARLES (1809–1882). Darwin was an English naturalist who is famous for his theory of evolution through the mechanism of natural selection. Even as a young boy, Darwin was always sensitive to the world around him. He was interested in collecting insects and enjoyed geology. Darwin may have been influenced by his grandfather Erasmus Darwin, who was a physician, scientist and wrote books with an evolutionary theme.

Interestingly, Darwin studied at Christ's College for a while because his father thought he would make a good parson. However, John Stevens Henslow, a professor of botany at Cambridge, recognized Darwin's knowledge on natural history and recommended he go on a surveying voyage for the Royal Navy to South America and across the Pacific to Australia.

In 1831, Darwin went on a five-year scientific expedition around the world aboard the H.M.S. Beagle, as the ship's naturalist. On the trip, he observed a variety of living things and also many marine fossils at the highest elevation of the Andes Mountains. Darwin also observed that species changed along the coast of South America, especially on the Galapagos Islands.

Darwin took careful notes on his trip and worked on his species idea for years and then published his observations and evolutionary theory through natural selection. His famous book, *The Origin of Species*. Darwin explained that species changed gradually over a long period of time by a process called natural selection, which is survival of the fittest. His theory based on his observations was supported by the fossil record, nistheory revolutionized biology.

In the later years of his life, Darwin wrote his book *The Descent of Man*, concerning the evolution of man. It became controversial and still is today. He continued developing his ideas and soon published *The Expression of the Emotions in Man and Animals* (1872).

Near the end of his life, Darwin spent time doing experiments on animal behaviors and plant responses. He will always be remembered as the most significant naturalist of the nineteenth century.

DATABASE. A commonly used term, essentially rendering the term data bank obsolete. In the very broadest sense, database refers to the collection of knowledge for use in some form of data processing system. For efficient and successful use in the computer processing of information, the database must be accurate and complete and thus requires a considerable effort to construct. As of the late 20th century, a succinct all-encompassing definition of database had yet to be written. The IEEE defines database (software) as: (1) a set of data, part or the whole of another set of data, and consisting of at least one file that is sufficient for a given purpose or for a given data processing systems; (2) a collection of data fundamental to a system; or (3) a collection of data fundamental to an enterprise. Hunt

defines database as a collection of data about objects and events on which the knowledge base will work to achieve desired results. A relational database is one in which the relationships between various objects and events are stored explicitly for flexibility of storage and retrieval. The set of facts, assertions, and conclusions used to match against the IF-parts of rules in a rule-based system. Olle observes that database is a more sophisticated concept than the older term *file*, which was carried over into data processing terminology from the pre-computer era. Unfortunately, it is all too frequently used when all that is implied is a conventional file. The difference between a database and a file, in terms used prior to the advent of data processing (electronic), is perhaps analogous to the difference between a thoroughly cross-referenced set of files in cabinets in a library or in an office and a single file in one cabinet that is not cross-referenced to any other file.

In very practical terms, a manufacturer who is contemplating the use of sophisticated robotics and other automation techniques must create a reliable database for use by the instrumentation and computer control system. Creating this database for the first time can be a tedious and time-consuming task — because manufacturing processes and operations that were formerly resident in the heads of production managers, supervisors, and foremen must be quantified and reduced to crisp facts that ultimately can be reduced to system symbology.

DATABASE MANAGEMENT SYSTEMS. By a database management system (DBMS) we refer to the software system that allows users to define, create, and maintain a database. The term database in this case refers to a collection of logically related data that is used and shared by the application systems of an enterprise. The term database is generally used to refer to the data itself; however, in a computerized database management system there are other additional components that need to be taken into account such as the hardware, the software itself, and the users. The latter can access or retrieve data on demand using the applications and interfaces provided by the database management system. Observe that in our definition the DBMS is a system layer that is between the physical data stored in files somewhere in the system and the users. The set of facts represented in a database is called the *Universe of Discourse* (UOD). The UOD should only include facts that in addition of forming a logically coherent collection are also relevant to the users. For these reasons, unlike common perceptions, a database management system is not a general repository of any data. Instead DBMSs are always designed, built, and populated for a particular audience and for a specific purpose. Some of the advantages that a database system offers over more traditional paper-based methods of record keeping are the speed with which up-to-date and accurate information can be retrieved on demand. Besides this a computerized database allows controlled access to the data while avoiding inconsistencies and enforcing security mechanisms and standards.

Database management systems are based on data models or logical representations of the data. The most commonly used data model is the relational data model, however, there are many legacy systems based on the most traditional hierarchical and network model. A DBMS based on the relational data model is referred to as a *Relational Database Management System* or RDBMS. Likewise, DBMSs based on the hierarchical and network data models are referred to as HDBMS or NDBMS. Current research concentrates on the objected oriented and semantic models.

The overall description of a DBMS is called the database schema. There are three different types of schema in the database: the external, internal, and conceptual. Each of these schemas is defined according to the specifications provided by the System Planning and Requirements Committee of the American National Standards Institute (ANSI/SPARC). (http://web.ansi.org/default is.htm). This set of specifications, known as the three-level architecture, is an abstract framework for describing the concepts and structures of any specific database system. The conceptual schema describes all the data items, the relationships among the different data items, and the conditions that the data need to be satisfied by the data (data constraints). There is only one conceptual schema per database. The internal schema is a complete description of the internal model. It contains the definitions of stored record, their representation, and the data fields that may comprise them. In addition, this schema contains the mechanisms to locate and retrieve the different data items. The conceptual level provides the corresponding mappings between the internal and external level. DBMS relates these schemas through mechanisms called mappings. Most of the current DBMS follow somewhat the ANSI/SPARC recommendations.

In addition to the description of the different schemas of a DBMS, the three-level architecture provides several additional benefits. For instance, it separates each user's view of the database from the way it is physically represented. This is desirable because the individual users of the database can access the same data while having different customized view of it. The three-level architecture also allows the implementation of changes to the internal structure of the database without having to change the users' views or the application programs (physical data independence). Finally, the three-level architecture also allows changes to the conceptual or global restructure of the database without affecting the users or the applications (logical data independence).

To create, maintain, and update all the database structures, most database systems provide at least two basic languages. These languages are called the *Data Definition Language* (DDL) and the *Data Manipulation Language* (DML). The DDL is used to describe all schemas of a DBMS. The DDL includes operations to create, update, and modify the structure of the database objects. For instance, in a relational database, the DDL allows the creation, update, and modification of the internal structure of all tables as well as the definition of any constraints that may be imposed on the data fields. The DML provides all the basic operations for retrieving, updating, inserting, and deleting items from the data held by the DBMS. For example, in a relational database, the DML allows the users to insert data into a table or update the content of any table or delete data from a table.

As we indicated before, DBMSs may be classified according to their underlying data model or some other criteria. DBMSs may be classified according to their number of users (single user or multi-users) or their mode of operation (centralized versus distributed). In a centralized system both the data and the DBMS reside at a single computer independent of the number of users. This is typical of many single-user environments. In multi-user environments, a distributed system has its data distributed over many sites with/without duplication of data. Each of these sites has it own DBMS and its own set of applications. In addition, each site can run applications at any of the other sites. If all of these sites have the same DBMS the distributed system is called a homogeneous system; otherwise it is called a *heterogeneous system*. For multi-users environments the client/server architecture is one of the most common configurations. In this configuration, users, generally connected through a local area network (LAN), run client applications on their local machines. These applications operate on a database, actually a full DBMS, which resides at another computer (the server).

From an operational point of view, a DBMS performs several important functions that guarantee the integrity and consistency of the data. Most of these functions can be achieved only through the DBMS itself and are transparent to the end user. Among the most important functions we find, data storage management, security management, multi-user access control, backup and recovery mechanisms, and communication interfaces. All these functions, although critical in most DBMS, are of extreme importance in the databases that are behind most web sites.

DATA LINK. Any communications channel or circuit used to transmit data from a sensor to a computer, a readout device, or a storage device.

DATE PALM. See **Palm Trees**.

DATOLITE. Datolite, basic calcium boron silicate, $CaBSiO_4(OH)$, occurs in monoclinic crystals of varied habit, mostly short stout prisms, but often in highly modified forms. Datolite reveals no cleavage, its fracture is conchoidal to uneven; brittle; hardness, 5–5.5; specific gravity, 2.9–3.0; luster, vitreous to dull; color, white to gray or may be greenish, yellowish, or brownish. It has a white streak and is transparent to translucent usually, but has been observed opaque.

Datolite is a secondary mineral, being found in veins and cavities associated with zeolites and calcite, particularly in the basic igneous rocks. It has been found in the Harz Mountains, Germany; in the Trentino district, Italy; in Norway and Tasmania. In the United States it has been found in the Triassic traps of the Connecticut River Valley in Massachusetts and Connecticut, and from similar rocks in New Jersey. In Michigan, datolite has been found associated with the copper-bearing rocks of Keweenaw County. This mineral derives its name from the Greek word meaning to divide, in reference to the granular structures of some of the massive varieties.

DATUM. Any numerical or geometrical quantity, or set of such quantities which can serve as a reference or a base for measurement of other quantities. For a group of statistical references, the plural form is data; as geographic data for a list of latitudes and longitudes. Where the concept is geometrical the plural form is datums; as in two geodetic datums have been used.

DAVAINE, CASIMIR-JOSEPH (1812–1882). Casimir-Joseph Davaine was a French medical doctor and microbiologist who made important contributions to early research in bacteriology and comparative pathology and parasitology.

Born into a family of distillers at St Amand-les-Eaux in 1812, Davaine was educated locally and at Lille before taking up medical studies in Paris at the end of 1830. Four years later he began an internship under Pierre Rayer (1793–1867) at the Charité Hospital, passing his doctorate in medicine at the Paris Faculty of Medicine in December 1837. Throughout the 1840s he practiced among an impressive list of society patients which included Napoleon III, members of the Rothschild family, and Alphonsine Plessis, the inspiration for Dumas's celebrated 'Dame aux Camélias', while enthusiastically joining Rayer in research in comparative pathology and bacteriology. In August 1850 Rayer announced at the Société de Biologie results, obtained with Davaine, of animal experiments comparing properties of blood of sheep inoculated with anthrax with samples from healthy animals, in order to distinguish between the discrete corpuscles in healthy blood and the irregularly agglutinated formations in anthrax blood. The resulting paper mentioned the presence in anthrax blood of 'small rod-shaped bodies'; but no attempt was made to explore any possible significance of the observation. It was nevertheless the first recorded observations of the anthrax bacilli they were later to call *bactéridies.* Five years later the German Alloys Pollender (1800–1879) claimed to have made the same observation in 1849 without publishing it. Davaine returned to the subject in the 1860s and preceded Koch and Pasteur in attempts to isolate the putative agent of anthrax, and demonstrate and clarify its role in the aetiology of the disease; but definitive evidence escaped him, unaware as he was of its resistant spore stage. See also **Immunology (The History)** and **Koch, Heinrich Hermann Robert (1843–1910)**.

Other contributions by Davaine included work on the larger parasites of humans and domestic animals. His *Traité des Entozoaires* (1860, 1877) was a first of its kind, and brought together knowledge and understanding of the subject based on his own and his contemporaries' research. His observations on teratology –the science of "monsters and monstrosities"' of humans and of animals –were mostly made during his years of association with Rayer, and presented at the Société de Biologie and published in its journals. His own studies in comparative parasitology included the first suggestion, in 1857, of tracing the presence of intestinal worms by looking for their eggs in the stools, a method brought to perfection more than 60 years later by Norman Stoll at the Rockefeller Institute, in his classic 'egg-counting' technique. See also **Parasitology (The History)**.

LISE WILKINSON, Wellcome Institute for the History of Medicine, London, UK

DAVYDOV SPLITTING. The splitting observed in absorption lines due to excited states in molecular crystals. In the simple case where there are two molecules in the unit cell in which the molecules are differently oriented, a doublet will be observed. The splitting results from the interaction between excited states of molecules within the cell.

DAVY, SIR HUMPHRY (1778–1829). Born in Cornwell, Davy was the first to isolate the alkali metals and recognize the identity of chemical and electrical energy. A pioneer in the science of electrochemistry, he carried out basic studies of electrolysis of salts and water, and his application of electricity to the decomposition of molten caustic potash led to the isolation of metallic potassium.

DAY. 1. A basic time increment defined by the earth's motion; specifically, a complete revolution of the earth about its own axis.

The sidereal day is defined as the time required for the earth to make one complete revolution in an absolute coordinate system, that is, with respect to the stars. See also **Sidereal Day**. The day in common use is the mean solar day, derived, by means of the equation of time, from the apparent solar day, which is determined directly from the apparent relative motion of the sun and earth. The civil day is a modification of the mean solar day, which renders it practical as a time measure for ordinary purposes. See also **year, lunar day**. 2. The period from midnight to midnight, local civil time; that is, a civil day. 3. The period of daylight, as opposed to that of darkness.

Apparent Solar Day

(Also called true solar day.) The interval of time between two successive transits of the sun across a meridian.

This interval is about four minutes longer than the sidereal day, largely because of the sun's apparent annual motion eastward along the ecliptic (actually, the earth's "westward" motion along its orbit), which motion delays the sun's return to meridional transit. Also, this interval is inconveniently nonuniform due to systematic variations in the earth's orbital speed around the sun and the sun's changing declination. The concept of the mean solar day has been invented to circumvent these practical difficulties.

Civil Day

A mean solar day reckoned from midnight to midnight, usually divided into two 12-hour divisions, although now often regarded as a single 24-hour series. As practically applied by use of meridional time zones of approximately 15° width, civil time is accurate (relative to mean solar time) to within ±30 minutes, or 7° of longitude. Minor exceptions occur when the time zones have been established according to geopolitical considerations, rather than adhering strictly to the meridians.

Lunar Day

1. (Also called tidal day.) The time required for the earth to rotate once with respect to the moon, that is, the time between two successive upper

transits of the moon. The mean lunar day is approximately 1.035 times as great as the mean solar day, or 24 hours 50 minutes.

2. In astronomy, the time required for the moon to revolve once, relative to a fixed star, about its own axis.

Mean Solar Day

The interval of time between two successive meridional transits of the "mean sun," an imaginary point moving with such constant angular velocity along the celestial equator as to complete one annual circuit in a time period exactly equal to that of the apparent (true) sun in its annual circuit. The mean solar day is 86 400 seconds, or 1.0027379 sidereal day. This modification of the apparent solar day was devised as a means of smoothing the irregularities observed in apparent relative motion of sun and earth; the equation of time defines the difference between the two. Outside astronomical circles, the mean solar day is the day in common use, but since it is reckoned from noon to noon, it has been modified to the civil day for practical use.

Observational Day

Any 24-hour period selected as the basis for climatologic or hydrologic observations. Where observations are recorded automatically, the observational day is commonly taken as the calendar day. Where only one observation is made in 24 hours, the observational day is assumed to be the 24 hours ending at the time of observation.

Pendulum Day

The time required for the plane of a freely suspended (Foucault) pendulum to complete an apparent rotation about the local vertical. This period τ is given by the formula

$$\tau = \frac{2\pi}{\Omega \sin \phi} = \frac{\text{sidereal day}}{\sin \phi}$$

where Ω is the angular speed of the earth and ϕ the latitude.

DAYLIGHT SAVING TIME. See **Time**.

DEACON PROCESS. A method of converting hydrogen chloride to chlorine by oxidation of hydrogen chloride with oxygen at 400–500 °C over a copper-salt catalyst, $2\ HCl + O \rightarrow Cl_2 + H_2O$. It is a means of producing chlorine without caustic and of utilizing the large amounts of by-product hydrogen chloride from the chlorination of organic compounds. When conducted in the presence of an organic compound that reacts with the chlorine formed, it is known as oxychlorination, e.g., $CH_2 = CH_2 + 2\ HCl + O \rightarrow CH_2ClCH_2Cl + H_2O$.

DEAD BAND (Instrument). The range through which an input can be varied without initiating a response. Dead band is usually expressed in percent of span. See figure which accompanies entry on **Hysteresis (Instrument)**.

DEAD CENTER. In machine tools, the term applies to the stationary center on which work rotates while being machined. In a lathe, the dead center is mounted in the tailstock. In heavy-duty lathes, the pressure on the pivot bearing effected by the center holes and the dead center is often so great that the dead center, or the center hole in the work, may wear excessively, and a rotating dead center, consisting of a center mounted in ball bearings carried in the shank that fits the tailstock sleeve, is often used. In grinding machines both centers are frequently stationary.

An engine is said to be on dead center when the piston is at one end of its stroke and the crank, connecting rod, and piston rod are in alignment. In this position, the pressure does not exert a rotative force on the crank, since it is transmitted directly to the shaft and bearings.

DEAD MEN'S FINGERS. 1. *Porifera*. A branching sponge, *Chalina arbuscula*, found off the Atlantic coast of the United States. Its branches are rounded finger-like projections of white or light gray color.

2. Coelenterate *Anthozoa—Alcyonium digitatum*. Colonial form of various shapes and sizes usually broad-lobed masses with polyps embedded in a fleshy mass attached to stones below tide marks.

DEAD RECKONING. The meaning of this navigation term can be best understood from a consideration of its probable origin. Early navigators deduced their positions at any time by using the distances and directions of motion of their ship since leaving some previously known position. Such positions were determined at frequent intervals and were entered in log books under a column headed by the abbreviation "ded. pos." The calculating or "reckoning" necessary to obtain the entries for this column was known as "ded reckoning," and is now written as dead reckoning.

Dead reckoning is fundamental for the methods of modern navigation, and should be clearly understood. Pilotage, radio navigation, celestial navigation, and other methods for determining positions of a ship or plane all involve the use of dead-reckoning methods. This is particularly true in a case where two lines of position are not observed simultaneously, and the fix must be found by moving one or both of the lines by dead reckoning.

There is a conflict of opinion among modern sea navigators as to just how much material should be included in the dead-reckoning (DR) position. It is certainly true that, originally, only the heading of the ship and the distance run on that heading were included. Some modern sea navigators cling to the original meaning of the term. The effects of current and leeway may be computed independently and the DR position corrected to an estimated position (EP). Some sea navigators include all known or suspected motions of the ship in their dead reckoning, and call the resulting position either DR or EP.

It is an established procedure in air navigation to include the movement of the plane through the air (heading and air distance), and the movement due to the motion of the air itself (wind direction and speed), in determining a DR position. In air navigation, the term estimated position (EP) is used in connection with celestial navigation, and is discussed in the article on that subject.

Before entering upon a discussion of actual methods of dead reckoning, it should be clearly understood that certain errors are bound to appear in the data employed in the calculations. These may be listed under five groups: compass corrections, steering, patent logs or air-speed meters, leeway of a seaborne ship, and predicted current or wind. Under the most favorable conditions, the dead-reckoning position is somewhere within a circle whose center is the DR position and whose radius is between 1 and 2% of the distance run. In conditions of rough sea or turbulent air, the radius may increase to more than 5% of the distance run.

The graphical method of solution is used by practically all air navigators and by a majority of those on the sea. This is essentially the graphical addition of vectors. In the determination of the old-fashioned DR position, the vectors used are total motions within given periods of time. These vectors are drawn to proper scale of distance on a mercator chart, mercator plotting sheet, or small-area plotting sheet, with the tail of the first vector resting on the last-known position, known as the point of departure, and the head of the final vector at the DR or EP position. All vectors must be properly labeled, the direction of each being the heading and the length proportional to the distance run.

The graphical method of solution is illustrated in the following case: At 1200, a ship is in latitude 43°35′ N and longitude 34°38′ W. At 1200, the ship is on heading 150°, speed 12 knots; at 1430, heading altered to 125°, speed 12 knots; at 2000, heading altered to 030°, speed 12 knots; at 2400, heading altered to 320°, speed 12 knots. The vector diagram is drawn on a small-area plotting sheet and properly labeled, as shown in Fig. 1. The various distances are obtained for the vectors by simply multiplying the speed by the time. From this diagram, the DR positions for any desired times can be read off directly. For example, the position at 1430 L = 43°09′.0 N and Lo = 34°17′.7 W and at 0400 L = 43°49′.5 N and

$$\text{Lo} = 33^\circ 12'.0\ \text{W}$$

In case a current is predicted for this region, an additional vector may be added to any DR position to obtain the estimated position. For example, if, in the above situation, we assume a current to set 240° with drift 3 knots, vectors (shown dotted in the figure) in direction 240° and lengths 7.5 and 48 miles are added at the 1430 and 0400 DR positions, respectively. This yields a 1430 EP L = 43°05.3 N and Lo = 34°26.6 W and 0400 EP L = 43°25.5 N and Lo = 34°09.4 W. If leeway is present, it should be treated as an additional compass correction to each heading, as explained in the article on leeway.

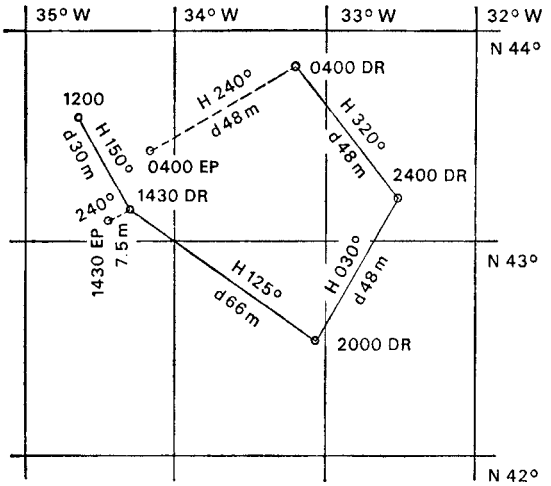

Fig. 1. Vector diagram used in dead-reckoning calculations.

The graphical method of solution for dead-reckoning problems requires a considerable amount of paraphernalia, e.g., plotting sheet, parallel rulers or protractor, scale, either pad and pencil or a dead-reckoning calculator for arithmetic computing, and, most important of all, a flat surface for doing the drawing. On large ships or planes, the navigator has the needed space, and the chart table is frequently equipped with a drafting machine, which simplifies the plotting. On small boats or planes, sufficient space for plotting is difficult to find. Computational methods are just as rapid as those involving plotting and they certainly yield more accurate results. However, it should be emphasized that the advantage of computational methods is only that of convenience in space, for the plotting methods are fully as accurate as the data warrant.

In the computational method, the first step is to solve the right triangle in which the heading vector is the hypotenuse, with the difference of latitude (DL) and the departure (dep) the two legs. The DL is added algebraically to the latitude (L_1) of the point of departure, calling DL + when north, and − when south. The DR latitude (L_2) is then $L_2 = L_1 + DL$. The departure must be converted from nautical miles to difference in longitude (DLo), in minutes of arc, by the method of middle-latitude sailing, using for the mid-latitude

$$L_m = \frac{L_1 + L_2}{2}$$

The DLo is added algebraically to the longitude (Lo_1) of the point of departure, calling DLo + when west, and − when east. The DR longitude (Lo_2) is then $Lo_2 = Lo_1 + DLo$. Three-place computing, using slide rule or traverse tables, is sufficient to attain all accuracy warranted by the data. To illustrate the computational method: At 0815 a ship is in latitude 41°42′ N and Lo = 35°25′ W. The ship proceeds along heading 243° at 14 knots, and the DR position at 1200 is desired.

L_1	41°	42.0 N	H	243°		Lo_1	35°	25′.0 W
DL		23.8 S	d	52.5 m		DLo	1	02′.5
L_2	41	18.2 N	dep	46.8 W		Lo_2	36	27′.5 W
			L_m	41°.5				
			DLo	62.5 W				

The actual numbers were read directly from traverse tables, and the total time required for solution was 2 minutes. The equipment used was a pencil, scratch pad, and traverse tables.

In more complicated cases, where a number of different headings and distances are used, and in a region where a current is predicted, we set up what is known as a traverse form, in which the columns N, S, E, and W refer to the direction of the individual DLs and departures. At 0400, a ship is on heading 200°, speed 15 knots, and is in latitude 40°21′.3 N and longitude 124°34′.6 W. AT 0723, the heading is altered to 300°, speed 15 knots; at 1136, heading altered to 030°, speed 15 knots; at 1314, heading altered to 340°, speed 15 knots. In this region there is a current setting 140° 2 knots. The traverse form used in determining the DR position at 1600 follows:

TRAVERSE FORM

H	Time	d	N	S	E	W
200°	3 h 23 m	50.8 m		47.7		17.4
300	4 13	63.3	31.8			54.9
030	1 38	24.5	21.2		12.2	
340	2 46	41.5	39.0			14.2
		Sums	92.0	47.7	12.2	86.5
		Total	44.3			74.3

L_1	40°	21′.3 N	dep	74.3 m W	Lo_1	124° 34′.6 W
DL		44.3 N	L_m	40°.7	DLo	1 37.9 W
L_2	41	05.6 N	DLo	97.9 W	Lo_2	126 12.5 W

To this DR position, the current motion must be added to attain the estimated position. The current motion in 12 hours is 24 miles along 140°, for which DL = 18.4 S, dep = 15.4 m E, and, in mid-latitude, 40°.7 DLo = 20.4 E. Applying these to the DR position, we have EP L = 40°47′.2 N and Lo = 125°52.1 W.

Whenever a fix is obtained, a DR position is also obtained. The difference between the two positions is always attributed to "current" by sea navigators, never to errors in their data or in obtaining the DR position. Here the difference in opinion as to whether or not leeway and current should be included in obtaining the DR position introduces confusion. If an old-fashioned DR position (i.e., without current or leeway included) is used, then the difference between fix and DR may be the actual current. If an EP is used, the difference between this position and the fix is a residual current, supplemental to that already used in the determination of the EP. In either case, the difference is called current, with set being equal to the direction from the DR position to the fix, and drift being the distance between the two positions divided by the number of hours elapsed from the point of departure for the dead reckoning. These so-called currents are entered in the ship's log book and later forwarded to the U.S. Coast and Geodetic Survey or other government agencies where statistical discussions yield improvements to previously predicted values.

In air navigation, a slightly different procedure for finding DR position is employed. In the first place, the work is always done by constructing the vector diagram. Before plotting the total distances from the point of departure, a velocity-vector diagram is used to determine the course and ground speed made good along this course. The heading and air speed of the plane are drawn as one vector, and to this is added the vector representing the direction toward which the wind is blowing and the wind speed. The vector sum is a vector giving course and predicted ground speed. Unfortunately, the first man to erect a weather vane balanced it so that the arrow pointed into the wind instead of with it. Still more unfortunately, the weather bureaus have retained this archaic method of publishing wind directions, and air navigators must be particularly careful in constructing their diagrams. After the course and ground speed along the course have been obtained, then a DR position can be obtained by plotting these in the same manner that the sea navigator plots heading and ship's speed. At 0916, a plane is known to be in latitude 41°52′ N and longitude 56°34′ W. The plane is heading 243°, with true air speed 110 knots, and the predicted wind is from 305°, speed 35 knots. The pilot wishes to determine the course and ground speed of the plane and the DR position at 1045. The vector-velocity diagram is shown in Fig. 2. The wind vector, *ew*, must be drawn in the direction in which the wind will move the plane, i.e., wind direction — 180°; to this is added the heading air-speed vector, *wp*. The sum, or vector, *ep*, is the course and speed made good. In this case, the course is found to be 225° and the ground speed 99 knots. With these quantities determined, the DR position is found by plotting the distance-vector diagram, shown in Fig. 3. The course 225° is laid off from the 0916 position on a mercator plotting sheet or a small-area plotting sheet, and the distance 99 × 1 h 20 m = 146 m is measured off on the proper scale, giving the 1045 DR position. If the heading is altered, a new velocity-vector diagram must be constructed and a new course and ground speed obtained. Then a distance vector would be added to that already found, and the DR position found at any desired time.

The solution of the velocity-vector diagram is facilitated by the use of any one of a number of dead-reckoning computers.

In case a reliable fix is obtained at the same time a DR position is found, and the two do not coincide, the air navigator always assumes that the difference is due to an error in the predicted wind. The line between the point of departure and the fix is known as the track if but one heading is used, or as the track made good if the plane has changed heading since

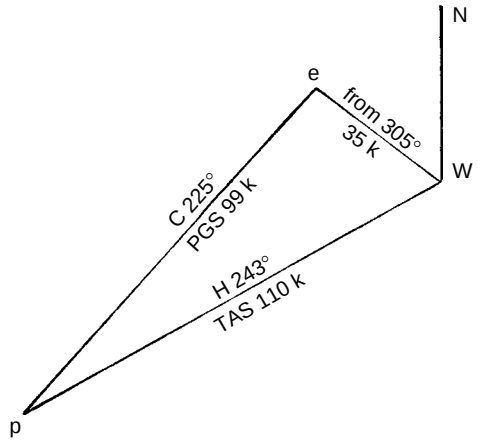

Fig. 2. Vector-velocity diagram used in dead-reckoning calculations.

DEAERATION. Because water dissolves, to a greater or lesser extent, many common gases, it will contain in the natural state a certain amount of dissolved gases, such as oxygen and carbon dioxide. Deaeration is the removal of this dissolved gas. Deaeration at the present is practiced where the gas that water contains would have undesirable effects. Often dissolved oxygen is objectionable because of its corrosive action. This is true in the case of the high-pressure steam boiler, where a small amount of oxygen dissolved in the feedwater may become quite active in attacking the boiler metal under the high pressure and temperature conditions there experienced. Steam boiler operators often treat their boiler feedwater in deaerators to remove this oxygen.

These deaerators are either of the deactivating or the heating type. Deactivating types employ chemical means of deaeration. Deaerating action in a heating-type deaerator is obtained by first reducing the solubility of the gas through heating the water (under pressure); second, reducing the pressure and producing explosive boiling; and third, controlling the agitation of the water subsequent to the second action in a partially evacuated region.

DEAFNESS. See **Hearing and the Ear**.

DEARDORFF VELOCITY. A velocity scale w^* for the convective mixed layer:

$$w^* = \left[\frac{g}{T_v} z_i \overline{w'\theta'_{vs}}\right]^{1/3},$$

where g is gravitational acceleration, T_v is absolute temperature, z_i is average depth of the mixed layer, $\overline{w'\theta'}_{v_s}$ is the kinematic vertical turbulent flux of virtual potential temperature near the surface.

The velocity scale is typically on the order of 1 m s^{-1}, which is roughly the updraft speed in convective thermals. This scale is often used in similarity theories for the convective mixed layer and was previously known as the convective velocity scale.

DEATH (Brain). A person presenting irreversible cessation of *all* functions of the entire brain, including the brainstem, is medically considered *brain dead*. Cessation of brain functions should be determined by clinical tests, which in some cases, should be supported by laboratory tests. Wherever possible, one or more physicians experienced in this diagnosis should be consulted as well.

Criteria supporting cessation of brain function include:

(1) Absence of cerebral functions and the presence of *deep coma*, where the individual does not indicate any cerebral responsivity. To assist in this confirmation, an encephalogram (EEG) and a blood flow study may be required.

(2) Absence of brainstem functions. Brainstem reflexes should be determined by an experienced physician, using adequate stimuli. Corneal, oculocephalic, oculovestibular, oropharyngeal, pupillary light, and respiratory (apnea) reflexes should be tested. If such tests cannot be fully and reliability evaluated, other confirmatory tests should be attempted.

Thorough testing for apnea is important. Ventilation with pure oxygen or an oxygen and carbon dioxide mixture for at least ten minutes before withdrawal of the ventilator is a correct procedure and this should be followed by passive flow of oxygen for a reasonable period. The procedure may be augmented by arterial blood gases testing. It must be assumed that *any* spontaneous breathing efforts indicate that part of the brainstem is still functioning.

Irreversibility is diagnosed when the following factors are definitely known: (1) cause of coma is sufficient to account for loss of brain functions; (2) possibility of recovery of any brain function is excluded; and (3) cessation of all brain functions persists for an appropriate period after observation and/or trials of therapy. After an irreversible condition is well established, and in the absence of confirmatory tests, a period of observation of a minimum of twelve hours is suggested and accepted by most physicians. Where anoxic damage is present, a period of observation of at least 24 hours is generally desirable for certainty.

Factors which complicate the determination of brain death include drug intoxication, particularly where several drugs may have been used. The cessation of brain functions may be completely reversible even in the presence of clinical cessation of brain functions and the brain is electrocebrally silent. Drugs that may be involved in reversible situations include sedative and anesthetic drugs, such as barbiturates, benzodiazepines, meprobamate, methaqualone, and trichloroethylene.

Physicians have pointed out that total paralysis may cause unresponsiveness, areflexia, and apnea that closely mimics death. Also a number of severe illnesses can cause deep coma, including hepatic encephalopathy, hyperosmolar coma, and preterminal uremia. In such instances, before irreversible cessation of brain function can be determined, any metabolic abnormalities should be considered and, where possible, treated. Confirmation tests would include circulation or an EEG.

Hypothermia (core temperature below 32.2 °C) also may mimic death. In hypothermic patients, the variables of cerebral circulation still are not well known. Certain phenomena associated with hypothermia appear to protect against neurological damage due to hypoxia. In addition, it is to be observed that hypothermia is a normal precedent of death. Fortunately, in a vast majority of instances, hypothermia is not a part of the patient's history, usually arising from rare kinds of accidents.

It is also important to observe that the brains of infants and young children possess relatively greater resistance to damage and sometimes may recover substantial brain function, although unresponsive on neurological examination. Particular caution must be exercised in diagnosing brain death in children under five years of age.

Physicians also should exert extreme caution in applying neurological criteria to determine brain death in persons in shock. Reduction in cerebral circulation can make the clinical examination of even laboratory tests unreliable.

Determination of brain death, as indicated in the foregoing paragraphs, is considerably less than a precise scientific procedure. Where potential organ transplantations from a brain-dead person are contemplated, there is always the danger of over anxiety and zealousness on the part of the professionals involved. Thus, there is a need for consensus among multiple experts. Numerous socio-scientific problems have arisen over the years, not only involving the brain-dead individual as an organ source, but also as a candidate for experimentation and research. For example, an experimental test carried out on a brain dead person in France reached the courts in 1988. See Dickson reference. The French Minister of health described the experiment as both "scientifically debatable" and "morally unacceptable."

In the case of anecephalic infants as organ donors, some professionals have suggested that the criterion for brain death is "the absence of integrative" brain function, such that *somatic* death is uniformly *imminent*. The point of emphasis here is that live-born anecephalic infants have not lost all integrative brain functions, but rather they are in the process of losing it. This implies that the infants are dying, but they are not dead. It is not clear how long the life span of such infants could be if provided with technical support. This emphasizes that dying is a process. Thus, the question is, whether an individual is brain dead (in legal terms) when the dying process commences not until the process has fully completed, representing a time interval that may vary in terms of hours or even weeks. As treatment procedures may be developed at some future date to treat such individuals, it would seem important to consider brain death to be the end of the dying process, not the beginning.

Presumed Consent. Various countries have different rulings regarding the interpretation of presumed consent in terms of the transplantation of certain organs from the brain dead. Because of the shortage of organs for transplantation and the importance of time in so many instances, some professionals observe that organ transplantation tends to be viewed in a one-sided manner — that is, emphasizing the problem from the perspective of the recipient rather than the donor source. The concept of brain dead requires further refinement in terms of scientific, moral, and sociological acceptance.

DEATH'S HEAD MOTH *(Insecta, Lepidoptera).* A large European sphinx moth, *Acherontia*, whose thorax bears a light mark shaped like a skull.

DEATH WATCH *(Insecta, Coleoptera).* A small beetle of the family *Anobiidae* which burrows in solid wood in buildings. By striking its head against the walls of the burrow it produces a sharp sound which can be heard in a quiet place.

DEBRIDEMENT. The treatment of wounds, especially traumatic, dirty, crushing wounds, by means of excising all injured, contaminated, or devitalized tissue, also, the division of any band of tissue constricting or compressing an organ.

DE BROGLIE ELECTRON THEORY. See **Electron Theory**.

DE BROGLIE, LOUIS-VICTOR (1892–1987). de Broglie was a remarkable French physicist. He studied at the Sorbonne in Paris, and although he entered as a history student, he later turned to science. He became a professor of theoretical physics at the Sorbonne in 1932. He was researching at about the same time that Arthur Compton, and de Broglie's s doctoral thesis showing the electron was demonstrated to have a wave character, made Compton's finding more significant. In 1923, de Broglie published three papers on light quanta. In his dissertation he described wave-particle duality, how matter waves should behave, and suggested it should be possible to diffract a beam of electrons using crystal. His theory advanced the study of physics significantly. For his work, de Broglie received the Nobel Prize in 1929. He wrote forty-five books on physics in his lifetime.

Professor de Broglie's most important publications are:

Recherches sur la théorie des quanta (Researches on the quantum theory), Thesis Paris, 1924.

Ondes et mouvements (Waves and motions), Gauthier-Villars, Paris, 1926.

Rapport au 5e Conseil de Physique Solvay, Brussels, 1927.

J. M. I.

DE BROGLIE WAVELENGTH. A wavelength ascribed to any particle having momentum. For a relativistic particle, the value of this wavelength is given by the expression:

$$\lambda = \frac{h}{m\nu} = \frac{h}{m_0\nu}\sqrt{\frac{1-\nu^2}{c^2}}$$

where λ is the de Broglie wavelength, h is the Planck constant, m_0 is the rest mass of the particle, ν is its velocity, and c is the velocity of light. The observed mass of the particle is m and the momentum is $m\nu$.

As an example, the wavelength of an electron moving with a kinetic energy of 1 eV (electron volt) is 1.23×10^{-7} cm, shorter than the wavelength $\lambda = c/\nu = hc/h\nu = 1.24 \times 10^{-4}$ cm for a photon with an energy of 1 eV, but longer than the wavelength of a proton moving with a kinetic energy of 1 eV, which is $\lambda = 2.86 \times 10^{-9}$ cm.

DEBUG. 1. To isolate and remove malfunctions from a device, or mistakes from a routine or program.

2. Specifically, in electronic manufacturing, to operate equipment under specified environmental and test conditions in order to eliminate early failures and to stabilize equipment prior to actual use. Also called *burn-in*.

DEBYE-FALKENHAGEN EFFECT. The variation of the conductance of an electrolytic solution with frequency. This effect, which is noted at high frequencies, is also called the dispersion of conductance.

DEBYE-HÜCKEL LIMITING LAW. The departure from ideal behavior in a given solvent is governed by the ionic strength of the medium and the valences of the ions of the electrolyte, but is independent of their chemical nature. For dilute solutions, the logarithm of the mean activity

is proportional to the product of the cation valence, anion valence, and square root of ionic strength giving the equation

$$-\log f_{\pm} = Az + z - \sqrt{\mu}$$

See **Electrochemistry**.

DEBYE, PETER J. W. (1884–1966). A Dutch chemist and physicist who received the Nobel Prize for chemistry in 1936 for his contributions to our knowledge of molecular structure through his investigations on dipole moments and on the diffraction of X-rays and electrons in gases. The interference patterns are still called Debye-Sherrer rings. He also made outstanding contributions to knowledge or polar molecules and to fundamental electrochemical theory.

DEBYE-SEARS EFFECT. A piezoelectric crystal vibrating in a longitudinal mode in a liquid sets up acoustic waves consisting of regions of compression and regions of rarefaction in the liquid, which alternate at distances of half a wavelength. Hence, if a parallel beam of light shines through such a crystal tank with plate-glass walls, the regions of density and rarefaction act like a plane light diffraction-grating. If the parallel beam from the cell is focused on a single spot when no sound waves are present, first and higher order diffraction-spectra will appear on either side of the zero-order spot when sound waves are present. From the spacings of the diffraction orders, the sound wavelength can be determined, which, together with the frequency, gives the velocity of sound in the liquid. See **Piezoelectric Effect**.

DEBYE THEORY OF SPECIFIC HEAT. The specific heat of solids is attributed to the excitation of thermal vibrations of the lattice, whose spectrum is taken to be similar to that of an elastic continuum, except that it is cut off at a maximum frequency in such a way that the total number of vibrational modes is equal to the total number of degrees of freedom of the lattice.

The Debye temperature is defined by the relation

$$\Theta = \frac{h\nu}{k}$$

where ν is the maximum frequency of the thermal vibrations of the lattice, h is Planck's constant and k is the Boltzmann constant.

DECALESCENCE. Absorption of heat, usually by an alloy, without rise of temperature, due to an allotropic transformation.

DE CANDOLLE, AUGUSTIN-PYRAMUS (1778–1841). Augustin-Pyramus de Candolle was a Swiss botanist and plant geographer who established the foundations of modern biogeography.

The Candolle family lived in Geneva, although Augustin-Pyramus de Candolle (known as Auguste) was born in the nearby town of Grandson, by Lake Neuchatel. On moving to Geneva in 1794, he attended medical school and botanized carefully in the surrounding countryside. He was greatly influenced by J. P. Vaucher, who encouraged him to think of preparing a European flora; by J. Senebier, who interested him in plant physiology; and by H. B. de Saussure, who introduced him to mathematics, philosophy and physics. After visiting Paris for his medical studies Candolle decided to settle there. Post-Revolutionary Paris was then by far the most exciting place to pursue scientific work and Candolle flung himself into all kinds of intellectual activity, joining the prestigious Société Philomatique, where he met Georges Cuvier and collaborated with Biot on the conductivity of gases, and the exclusive Société d'Arcueil, where he concentrated on problems of experimental science relating to physics and chemistry, especially on the properties of the atmosphere and light. He became good friends with Alexander von Humboldt during this time, publishing several physiological studies and analytical systematic works. He revised Jean-Baptiste Lamarck's *Flore Française* for a third edition in 1805 after visiting many districts in France. See also **Cuvier, Georges Leopold Chretien Frederic Dagobert Baron de (1769–1832); Humboldt, Alexander von; Lamarck, Jean-Baptiste Pierre Antoine de Monet de**; and **Plant Sciences (The History)**.

In 1808 he accepted the professorship of botany at Montpellier medical school, where he remained until tempted back to Geneva (newly independent from French rule) with a chair specially created for him in natural history. Thereafter, he energetically reorganized the botanic garden, created a museum of natural history, and was associated with numerous cultural and institutional improvements around the city. He wrote many useful articles on medical botany, pharmacology, plant pathology, monstrosities and agricultural botany, and proposed a concept of plant symmetry that had lasting impact on ideas about floral morphology. However, his most significant taxonomic work was the magisterial *Prodromus Systematis Naturalis Regni Vegetabilis*, published in sections from 1824 to 1839 and continued by his son Alphonse and other collaborators after his death. This was based on extensive knowledge of original specimens and consultations with other European experts. In it, he treated plants according to the natural system and discussed a wide variety of botanical questions, including physiology, geographical distribution, historical origins, affinities, ecology and agronomy.

Candolle is best known to posterity, however, for his important studies on plant geography in which he laid out the fundamental scientific principles of the field. His *Essai Elementaire de Geographie Botanique* (1820) was considered a masterpiece in its day, showing the close relationships between plants and soil which influence the distribution of vegetation, and was highly praised by Humboldt and Darwin among others. Candolle carefully distinguished the larger concerns of phytogeography from what has come to be known as ecology; and discussed both at a level of philosophical detail previously little seen. He coined the term 'station' (habitat in modern terms, e.g. moorland, marsh or coastline), analysed competition between individuals, calling it 'war in nature', and stressed the role of the environment in large distribution patterns which he called 'habitations' (botanical provinces, e.g. the habitation of rice is India). After he set out these principles, the study of plant geography attracted much attention, playing an important role in Charles Lyell's, Alfred Russel Wallace's and Charles Darwin's thoughts about adaptation and evolution. See also **Biogeography (The History)**; **Lyell, Sir Charles (1797–1875)**; and **Wallace, Alfred Russel (1823–1913**.

JANET BROWNE, Wellcome Institute for the History of Medicine, London, UK

DECAPODA. 1. The shrimps and prawns, lobsters, crayfishes, and crabs, constituting a large and important order of crustaceans. The thorax is covered by a carapace and bears five pairs of appendages, the first pair chelate grasping structures and the remaining four formed for walking.

2. The cuttlefish, squids and related forms, constituting an order of cephalopods. They possess ten arms, with stalked suckers provided with horny rims, and have a well-developed internal shell.

DECARBURIZATION. Reduction in carbon content at the surface of steel or cast iron by heating in air or other oxidizing or reducing gases. In heating for hot rolling, forging, or heat treatment, decarburization is usually objectionable, and specially prepared neutral furnace atmospheres may be used to reduce or eliminate it. Molten salt or lead baths are also effective in protecting the surface during heat treatment.

In the case of heat-treated machine parts, surface decarburization is objectionable because it reduces fatigue strength and lowers the wear-resistance of bearing surfaces. Important surfaces of hardened steel parts are often finish-ground, in which case a limited amount of decarburized skin can be removed. Tool steels for cutting tools, punches, chisels, etc., are usually ground sufficiently to remove all decarburization; however, many tools and dies are machined to finish dimensions before hardening and extreme care must be taken to protect the surface.

Decarburization is intentional in the processing of low-carbon sheet steels for electrical applications. In the production of malleable cast iron by annealing white cast iron decarburization is beneficial.

DECAY CONSTANT. The magnitude of some processes diminishes in accordance with an exponential function of the time; such as, for example, phosphorescence and radioactive radiations. The falling off or "decay" of such a process may be represented by an equation giving the intensity at the end of a time interval t as $I = I_0 e^{-ct}$, in which I_0 is the intensity at the beginning of the time interval and c is the "decay constant." Closely related to c is the half-value period, which is the time required for I to fall to $\frac{1}{2}$ its original value I_0; it is equal to $0.69315/c$. Thus, for example, because the half-value period of radium B is 1,608 seconds, c is $0.69315/1608$ seconds $= 0.000431$/second. This

means that approximately 0.000431 of the substance existing at any instant disintegrates during the ensuing second. The reciprocal of c, called the mean life or, under certain circumstances, the relaxation time, represents the time required for I to diminish to $1/e$ or 0.3697 of its original value I_0. It is equal to 1.4427 times the half-value period; for the decay of radium B its value is therefore 2,320 seconds. See Fig. 1.

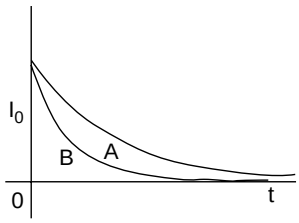

Fig. 1. Typical exponential decay curves. The decay constant in B is greater than in A.

DECAY PRODUCT. A nuclide resulting from the radioactive disintegration of a radionuclide, being formed either directly or as the result of successive transformations in a radioactive series. Also called *daughter*, or *daughter element*. A decay product may be either radioactive or stable.

DECAY TIME. 1. In computer operations, the time required for a pulse to fall to one-tenth of its peak value.

2. In charge-storage tubes, the time interval during which the magnitude of the stored charge decreases to a stated fraction of its initial value. The fraction is usually $1/e$ where e is the base of natural logarithms.

3. Approximately the lifetime of an orbiting object in a nonstable orbit. Decay time is usually applied only to objects with short orbit lifetimes caused by atmospheric drag.

DECCA. A long-range, ambiguous, two-dimensional navigation system using continuous-wave transmission to provide hyperbolic lines of position through the radio frequency phase comparison techniques from four transmitters. Frequency band, 68 to 150 kilocycles.

DECHLORINATION. Dechlorination is the practice of removing all or a specified fraction of total residual chlorine. In potable water practice, dechlorination is used to reduce the residual chlorine to a specified level at a point where the water enters the distribution system. Dechlorination has been beneficial for waters that are burdened with high concentrations of ammonia nitrogen and organic nitrogen. In some cases where taste and odor control is a severe problem, control is achieved by complete dechlorination, followed by rechlorination. This removes the taste-producing nuisance residuals and prevents the formation of nitrogen trichloride (NCl_3) [CAS: 100025-85-1] in the distribution systems. Dechlorination of wastewater and power plant cooling water is required to eliminate residual chlorine toxicity, which is harmful to the aquatic life in the receiving waters. Other special applications requiring dechlorination are ahead of demineralizers, boiler makeup water, certain food plant operations, bottled water, and the beverage industry. In these cases, the dechlorination process is arranged to remove all residual chlorine.

The most practical method of dechlorination is by sulfur dioxide and/or aqueous solutions of sulfite compounds. Among sulfur/sulfite compounds, sulfur dioxide (SO_2) [CAS: 7446-09-5] is the most widely used chemical for dechlorination. Other compounds such as sodium bisulfite ($NaHSO_3$) [CAS: 7631-90-5] and sodium metabisulfite ($Na_2S_2O_5$) [CAS: 7681-57-4] can be used as practical alternatives to sulfur dioxide. Sodium thiosulfate ($Na_2S_2O_3$) [CAS: 7772-98-7] is anothxer chemical that is used entirely as a laboratory dechlorinating chemical. Other methods used for dechlorination are granular-activated carbon and aeration.

Free and combined residual chlorine can be effectively reduced by sulfur dioxide and sulfite salts. Free chlorine is the amount of chlorine available as dissolved chlorine gas (Cl_2), hypochlorous acid (HOCl) [CAS: 7790-92-3], and hypochlorite ion (OCl^-) that is not combined with ammonia (NH_3) [CAS: 7664-41-7] or any other compounds in water. Combined chlorine is the sum of species composed of free chlorine and ammonia, including monochloramine (NH_2Cl) [CAS: 10599-90-3], dichloramine ($NHCl_2$) [CAS: 3400-09-7], and trichloramine or nitrogen trichloride (NCl_3) [CAS: 10025-85-1]. The sulfite ion is the active agent when sulfur dioxide or sulfite salts are dissolved in water. Their dechlorination reactions are identical. Sulfite reacts instantaneously with free and combined chlorine. Reactions yield small amounts of acidity, which is neutralized by the alkalinity of water (2.8 milligrams of alkalinity as calcium carbonate is consumed per milligram of chlorine reduced). Most potable waters and wastewaters have sufficient alkalinity buffering power that there is no cause for concern about lowering the pH by sulfur dioxide addition. The amount of sulfur dioxide required per part of chlorine is 0.9, but in actual practice, this ratio can be as high as 1.05. Owing to the low vapor pressure of sulfur dioxide, special precaution must be taken when using ton containers to prevent reliquefication. Unlike chlorination, dechlorination with sulfur dioxide does not require any contact chamber as the reaction occurs in a matter of seconds, probably 15–20 s at the most. There has been some apprehension about the possibility that excess sulfur dioxide might consume a significant amount of dissolved oxygen in the receiving waters downstream from a dechlorinated water discharge. In properly controlled systems, this reaction does not have sufficient time for completion. Hence, little effect on dissolved oxygen concentration has been reported.

Granular and powdered carbon may be used to dechlorinate free, and some combined, chlorine residuals. The carbon requirements for dechlorination are typically determined by on-site pilot testing. The parameters of significance include mean particle diameter of carbon (pressure drop within the carbon contactor) and influent quality (pH, organics, and colloids). Carbon doses in the range of 30 to 40 mg/L have been reported. Granular-activated carbon (GAC) has proved effective and reliable as a dechlorination agent in potable water treatment. In addition, carbon provides filtration that removes other undesirable materials. In wastewater treatment, however, GAC has not been successful as a dechlorinating agent, possibly, because GAC is poor at removing organochloramines that form when significant concentrations of organic nitrogen are present. Because of the higher cost of carbon systems, their use is typically limited to specific sites or effluent with special discharge limitations. An aeration process can be used for dechlorination. Chlorine, hypochlorous acid, chlorine dioxide, and nitrogen trichloride are sufficiently volatile to be removed by aeration.

DECIBEL (DB). A logarithmic measure of the relative power, or of the relative values of two flux densities, especially of sound intensities and radio and radar power densities.

The difference n in decibels between intensities I_2 and I_1 is given by the relation

$$n = 10 \log_{10}\left(\frac{I_2}{I_1}\right).$$

Although the decibel is a measure of relative rather than absolute intensity, it is possible to set up an absolute scale by arbitrarily defining some particular intensity or power level as a reference. For radar, the convention is to measure the received power in units of milliwatts and to define 1 mW as the reference value for a decibel scale. The units are then called dBm, or decibels relative to a milliwatt. The radar reflectivity factor, Z, is measured logarithmically on a scale of dBZ, on which the reference value is $Z = 1\ \text{mm}^6\ \text{m}^{-3}$. In acoustic practice, an intensity of $10^{-10}\ \mu\text{W cm}^{-2}$ is taken as the reference intensity. This value corresponds closely to the minimal threshold of audibility of the human ear. The decibel is derived from the less frequently used unit the bel, named in honor of Alexander Graham Bell (1847–1922). Two flux densities differ by 1 bel (10 dB) when the larger is 10 times greater than the smaller. It is to be noted

that the logarithmic nature of the response of sensory organs, described in the Weber–Fechner law, underlies the definition of the bel.

AMS

DECIDUOUS PLANTS. Plants that drop their leaves at the end of the growing season.

DECISION FUNCTION. A decision function is a rule of conduct which, at any stage of a sampling investigation, tells the statistician whether to take further observations or whether enough information has been collected, and in the latter case, what decision to make upon it. At each stage beyond the first, the decision function is a function of the preceding observations. Until the development of sequential analysis decision functions were mostly of the simple type, based on a fixed sample size, which enjoined the acceptance or rejection of a hypothesis or set limits to a parameter under estimate. The above definition provides for a sequential situation wherein the investigator may not reach a decision about the hypothesis but proceeds to take further observations.

DECLINATION. The declination of a celestial object is the coordinate in the equatorial system of spherical coordinates measured in the plane of the hour circle through the object from the equator to the object. In case the object is between the equator and the north celestial pole, the declination is said to be north or positive (+); otherwise, the declination is south or negative (−). Declination is ordinarily measured either with a meridian circle or an altazimuth instrument.

The term declination is used by surveyors, and a few others, in place of the term variation to describe the angle between true and magnetic north. Navigators, both air and sea, always use the term variation for this angle. See also **Celestial Sphere and Astronomical Triangle**.

DECODER. 1. A device for translating electrical signals into predetermined functions.

2. In computer operation, a network or device in which one of two or more possible outputs results from a prescribed combination of inputs. Also called *many-to-few matrix*.

DECOLORIZING AGENT. A substance that removes color by a physical or chemical action. Charcoals, carbon blacks, clays, earths, activated alumina or bauxite, or other materials of highly adsorbent character are used to remove undesirable colors (and often odors) from sugar, vegetable and animal fats and oils, and other substances. In a broad sense, decolorizing agents also embrace bleaches, which usually remove color by chemical reaction.

Activated carbon is one of the most widely used of the adsorbants. It is an amorphous form of carbon characterized by high adsorptivity. The carbon is obtained by the destructive distillation of wood, nut shells, animal bones, or other carbonaceous material. It is "activated" by heating to 800–900 °C with steam or carbon dioxide, which results in a porous internal structure. The internal surface area of activated carbon averages about 10,000 square feet (929 square meters) per gram. Numerous uses include applications in the brewing and sugar refining industries.

Diatomaceous earth also finds numerous adsorbant applications in food and chemical processing, not only in decolorizing, but as a filter aid and clarifying agent as well. This is a soft, bulky solid material (88% silica) composed of skeletons of small prehistoric aquatic plants related to algae. See also **Diatom**. They have intricate geometric forms and expose a great deal of area per unit of weight.

Fuller's earth, also used as an adsorbant, is a porous colloidal aluminum silicate (clay) which has a high natural adsorptive power. See also **Fuller's Earth**.

Silica gel is a regenerative adsorbant consisting of amorphous silica derived from sodium silicate and sulfuric acid. In addition to color adsorbing and bleaching powers, silica gel is used as a dehumidifying and dehydrating agent and as an anticaking agent.

Prior to crystallization in the refining of sugar, bleaching of the syrup is required. This is sometimes effected through treatment of the solution with calcium hypochlorite, usually in the presence of calcium phosphate which serves as a buffer and aids in the final precipitation of calcium from the bleached solution.

The physical properties of representative adsorbants and decolorizers are given in table in entry on **Adsorption Operations**.

DECOMPOSITION (Chemical). A chemical change in which a single chemical substance is broken up into two or more other substances, which differ from each other and from the parent substance in chemical identity. Complete decomposition refers to such a condition of the products that they are not readily decomposed further, e.g., such decomposition products as ammonia and carbon dioxide. *Degradation* refers to gradual decomposition in which the molecule is diminished in size in small steps. See also **Degradation (Chemical)**.

The *heat of decomposition* is the change of heat content when one mole of a compound is decomposed into its elements. This is equal in quantity, but opposite in sign, to the *heat of formation.*

Sensitized decomposition is a chemical decomposition that is brought about by the presence of a second substance which absorbs an exciting radiation. The essential mechanism of the reaction is the excitation of particles of the second substance by the radiation, followed by collisions between these excited particles and molecules to be decomposed. The process proceeds most effectively if the energy difference between the ground state and excited state of the sensitizer is nearly equal to the energy of the decomposition reaction.

Double decomposition is a term used to express the interaction of molecules which exchange one or more of their constituent atoms or radicals.

DECOMPOSITION VOLTAGE. The minimum electromotive force which must be applied to a given solution and given electrodes to produce steady electrolysis. The value of the decomposition voltage is not known precisely because the rise in a current-voltage curve does not begin at a sharply defined point. Instead the curve at first rises very slowly with increasing applied voltage; in the neighborhood of the decomposition voltage there is an abrupt change in slope (a sharp bend) and thereafter the curve rises rapidly with applied electromotive force.

DECOMPRESSION SICKNESS. A disorder experienced by deep sea divers and aviators caused by reduced atmospheric pressure and evolved gas bubbles in the body, marked by pain in the extremities, pain in the chest (chokes), occasionally leading to serve central nervous symptoms and neurocirculatory collapse.

DECOUPLING. A process where one layer of the atmosphere stops interacting with an adjacent layer. An example is a stratocumulus-topped turbulent boundary layer during the night, where infrared radiative cooling of cloud top causes cold "thermals" to sink toward the ground, causing strong turbulent coupling between the cloud and subcloud layers. During the day, these two layers can become decoupled as the combination of solar heating and infrared cooling in the cloud layer combine to make the cloud layer warmer than the subcloud layer, with a weak stable layer in between that reduces or prevents turbulent coupling of the two layers. These turbulently decoupled layers might still interact (i.e., be slightly coupled) in other ways, such as via radiation or drizzle fallout.

DECOUPLING FILTER. In most multistage amplifiers there are certain circuits, such as voltage supplies, common to more than one state. Since these common circuits provide a path through which energy may be fed from the output back into the input of some stages, serious feedback problems would result if something were not done to prevent them. The usual remedy is to insert a decoupling filter in those voltage supply leads that are common to more than one amplifier stage. These filters are frequently resistances in series with the lead and a bypass capacitor from the device (tube or transistor) side of the resistor to ground. The resistance used must be low enough not to cause a serious loss of voltage and the capacitor should have a reactance which is low compared with the resistance at the lowest frequency for which the circuit is designed. Where the resistance would produce too much D.C. voltage drop or where it does not give enough filtering action an inductance is sometimes used. For still more effective filtering a second resistance and condenser in cascade may be used.

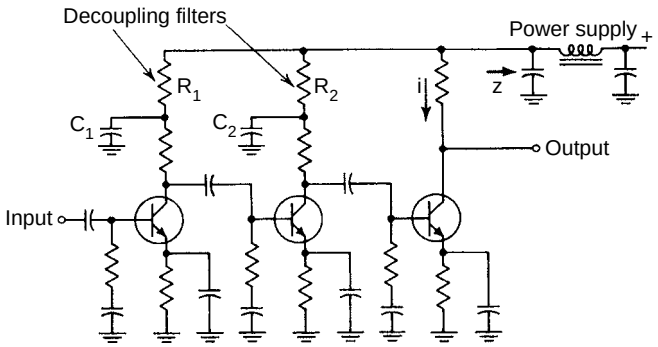

Fig. 1. Decoupling filters used in three-stage transistor amplifier.

A practical amplifier employing decoupling filters is shown in Fig. 1. The signal current i flowing in the collector circuit of the third transistor develops a voltage iZ across the output terminals of the power supply. The voltage developed across the impedance Z will cause additional components of signal current to flow in the base circuits of the second and third transistors. Use of the elements R_1, C_1 and R_2, C_2 causes a reduction of the signal fed back to an amount that does not deteriorate the amplifier performance appreciably. See also **Filter (Communications System)**.

DECREMENT GAGE. A gage in which pressure is measured by the rate of decay in amplitude of the oscillations of an element suspended in the gas and set into motion by external controls. Also known as *decrement viscosity gage* or *viscosity manometer*. Various types of decrement gage are distinguished according to the design of the oscillating element.

DECREPITATION. The emission of a crackling sound, commonly by crystals on shattering under the internal stresses resulting from heating.

DEDIFFERENTIATION. A process of change from a more specialized to a less specialized condition.

DEEP SCATTERING LAYER. During the day zooplankton sink substantially below the ocean's surface, to which they rise again in the night. This migration can be detected by echo sounding devices as a "bottom" at mid-depth and is referred to as the "deep scattering layer." The cause of the daily migration is believed to be an aversion to light.

DEEP SPACE NETWORK. NASA's scientific investigations of the solar system are accomplished mainly through the use of robotic spacecraft. The Deep Space Network (DSN) provides the two-way communications link that guides and controls spacecraft and brings back images and other scientific data they collect.

The Deep Space Network encompasses complexes strategically placed on three continents. The largest and most sensitive scientific telecommunications system in the world, it also performs radio and radar astronomy observations for the exploration of the solar system and the universe. It is managed and operated for NASA by the Jet Propulsion Laboratory (JPL).

The predecessor to the DSN was established in January 1958 when JPL, then under contract to the U.S. Army, deployed portable radio tracking stations in Nigeria, Singapore, and California to receive signals from — and plot the orbit of — *Explorer 1*, the first successful U.S. satellite.

On December 3, 1958, JPL was transferred from Army jurisdiction to that of the newly created NASA and given responsibility for the design and execution of robotic lunar and planetary exploration programs. Shortly afterward, NASA established the concept of the DSN as a separately managed and operated communications facility that would accommodate all deep space missions, thereby avoiding the need for each flight project to acquire and operate its own specialized space communications network.

By 2000 the DSN featured three deep-space communications complexes placed approximately 120 degrees apart around the world: at Goldstone in California's Mojave Desert; near Madrid, Spain; and near Canberra, Australia. This configuration ensures that an antenna is always within sight of a given spacecraft, day and night, as the Earth rotates. Each complex contains up to 10 deep-space stations equipped with large parabolic reflector antennas.

Antennas and Facilities

Each of the DSN complexes has one 70-meter-diameter (230-foot) antenna. These are the largest and most sensitive of DSN's antennas, capable of tracking spacecraft traveling more than 16 billion kilometers (10 billion miles) from Earth. The surface of the 70-meter reflector must remain accurate within a fraction of the signal wavelength, meaning that the precision across the 3,850-square-meter (4,600-square-yard) surface is maintained within one centimeter (0.4 inch). The dish reflector and its mount weigh nearly 2.7 million kilograms (8,000 U.S. tons). See Figs. 1–3.

Each complex also has a 34-meter-diameter (112-foot) high-efficiency antenna, incorporating more recent advances in antenna design and mechanics. The reflector surface is precision-shaped for maximum signal-gathering capability. See Figs. 4 and 5 on pp. 1037 and 1038.

The most recent additions to the DSN are several 34-meter beam waveguide antennas. See Fig. 6 on p. 1038. On earlier DSN antennas, sensitive electronics were centrally mounted on the hard-to-reach reflector structure, making upgrades and repairs difficult. On beam waveguide antennas, however, such electronics are located in a below-ground pedestal room, with the radio signal brought from the reflector to this room through a series of precision-machined radio frequency reflective mirrors. Not only does this architecture provide the advantage of easier access for enhancements and maintenance, but it also allows for better thermal control for critical electronic components and for more electronics to be placed in the antenna to support operation at multiple frequencies. Three of these new antennas have been built at Goldstone, along with one each at the Canberra and Madrid complexes.

There is also one 26-meter-diameter (85-foot) antenna at each complex for tracking Earth-orbiting satellites, which are in orbits primarily 160 to 1,000 kilometers (100 to 620 miles) above Earth. The two-axis astronomical mount allows these antennas to point low on the horizon to pick up fast-moving Earth-orbiting satellites as soon as they come into view. They can track at up to three degrees per second.

Each complex has also recently added one 11-meter (36-foot) antenna to support a series of international Earth-orbiting missions under the Space Very Long Baseline Interferometry project.

All of the antennas communicate directly with the Deep Space Operations Center at JPL in Pasadena, California. The center staff directs and monitors operations, transmits commands, and oversees the quality of spacecraft telemetry and navigation data delivered to network users.

In addition to the DSN complexes and the operations center, a ground communications facility provides communications linking the three complexes to the operations center at JPL, to flight control centers in the United States and overseas, and to scientists around the world. Voice and data traffic between various locations is sent via land lines, submarine cable, microwave links, and communications satellites.

The Radio Link

The Deep Space Network's radio link to spacecraft is basically the same as other point-to-point microwave communications systems, except for the very long distances involved and the very low spacecraft signal strength: the total signal power arriving at a network antenna from a spacecraft encounter among the outer planets can be 20 billion times weaker than the power level in a modern digital wristwatch battery.

The extreme weakness of the signal results from restrictions placed on the size, weight, and power supply of the spacecraft by the cargo area and weight-lifting limitations of the launch vehicle. Consequently, the design of the radio link is the result of engineering tradeoffs between spacecraft transmitter power and antenna diameter, and the sensitivity that can be built into the ground receiving system.

Typically, a spacecraft signal is limited to 20 watts, or about the same power as required to light a refrigerator bulb. When the signal arrives at Earth from outer space — say, from the neighborhood of Saturn — it is spread over an area with a diameter equal to about 1,000 Earth diameters. As a result, the ground antenna is able to receive only a very small part of the signal power.

In addition, the signal is degraded by background radio noise, or static. Noise is radiated naturally from nearly all objects in the universe, including

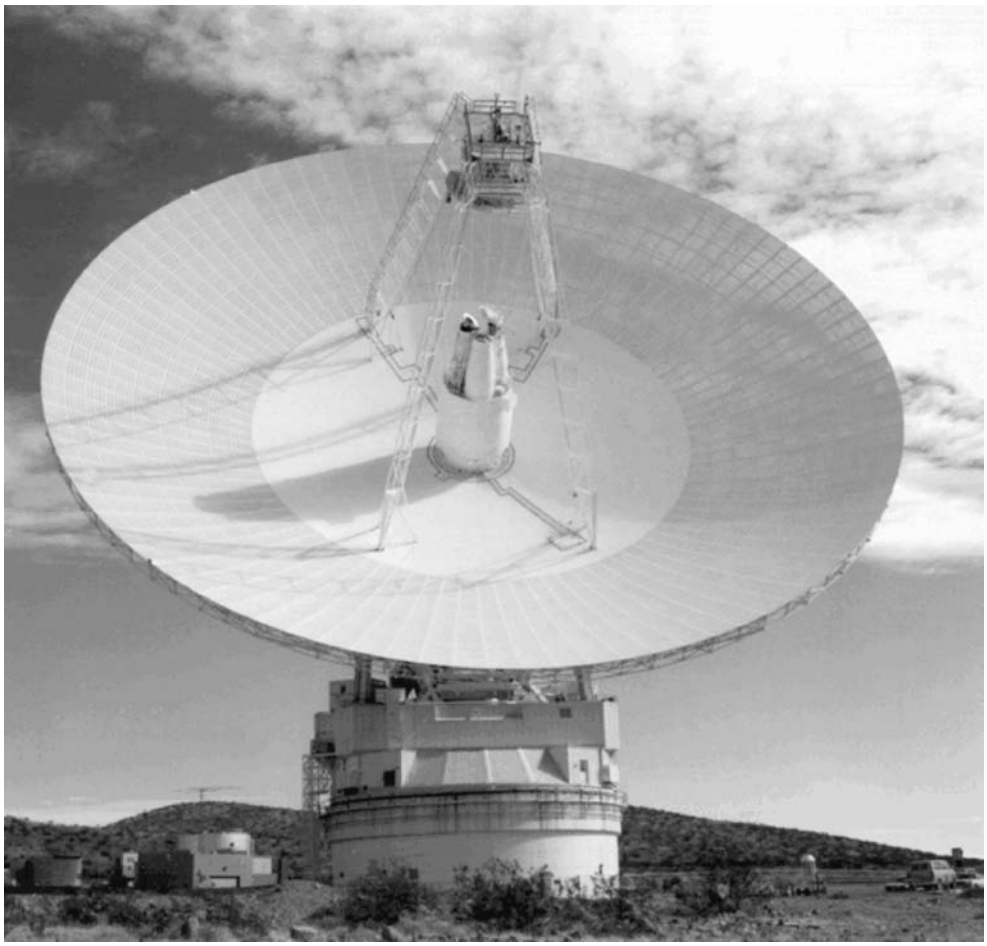

Fig. 1. Front view of the 70-m antenna at Goldstone, California. (*Jet Propulsion Laboratory; California Institute of Technology; NASA, Pasadena, California.*)

Earth and the sun. Noise is also inherently generated in all electronic systems, including the DSN's own detectors. See also **Noise**.

Since there will always be noise amplified along with the signal, the ability of the ground receiving system to separate the noise from the signal is critical. The DSN utilizes state-of-the-art, low-noise receivers and telemetry coding techniques to create unequaled sensitivity and efficiency.

What is telemetry? It is the transmission of data to or from a spacecraft by radio waves. For spacecraft sending messages to Earth, telemetry is engineering data and information about the spacecraft's own systems, produced by its own scientific instruments. It is transmitted in binary code, using only the symbols 1 and 0.

The spacecraft organizes and encodes data for transmission to ground stations which have equipment to detect the individual bits, decode the data stream and format the information for transmission to the data user.

That transmission can be disturbed by noise from various sources that interferes with the decoding process. If there is a high signal-to-noise ratio (SNR), the number of decoding errors will be low. But if the signal-to-noise ratio is low, bit errors can be excessive; the data transmission rate, measured in bits per second, must be reduced to give the decoder more time to determine the value of each bit.

To help solve the noise problem, additional or redundant data are fed into the data stream and are used to detect and correct errors after transmission. The equations used in this process are sufficiently detailed to allow individual and multiple errors to be detected and corrected. After correction, the redundant digits are eliminated from the data, leaving a validated sequence of information to be delivered to the data user.

Error detecting and encoding techniques can increase the data rate many times over transmissions that are not coded for error detection. DSN coding techniques have the capability of reducing transmission errors in spacecraft science information to less than one in a million.

But telemetry is a two-way street. Commands, computer software, and other crucial data can be transmitted up to our spacecraft, providing the ability to guide the spacecraft on their planned missions, as well as to upgrade a spacecraft's onboard software, among many other capabilities, in order to enhance mission objectives.

Data collected by the DSN is also very important for precisely determining a spacecraft's location and trajectory. This tracking data is used by mission navigator teams to plan all the maneuvers needed to ensure that the spacecraft is at the right place to collect its valuable scientific data. This tracking data allows the location of a spacecraft that is billions of kilometers from Earth to be determined to an accuracy of just a few meters.

Arraying Antennas

When a single antenna is unable to capture a spacecraft signal by itself, the DSN uses a technique called "arraying" to combine the signal from two or more antennas. The improvement in performance from arraying may be the only way to capture an extremely weak signal, or, in some cases, to allow for a higher data rate. The DSN's ability to array its own antennas together, as well as arraying with antennas from other agencies, has been used several times to increase the science data capture from deep space missions.

A dramatic example of arraying on an international scale came in the fall of 1996. An intercontinental link-up of the DSN's antennas in Australia and Goldstone was developed to retrieve the maximum amount of data possible from NASA's Galileo spacecraft, whose planned high-speed, high-power telecommunications voice had been reduced to a whisper when its main antenna failed to open four years earlier. The combining of the signals from up to four DSN antennas, plus the Parkes Radio Telescope in Australia, operated by the Commonwealth Scientific and Industrial Research Organization (CSIRO), together with new data encoding techniques, increased the raw data return over ten times what would have otherwise been possible.

The DSN has also used antennas from other international agencies to help support arraying efforts for the Voyager project's successful fly-bys of Uranus and Neptune. These antennas included the twenty-seven

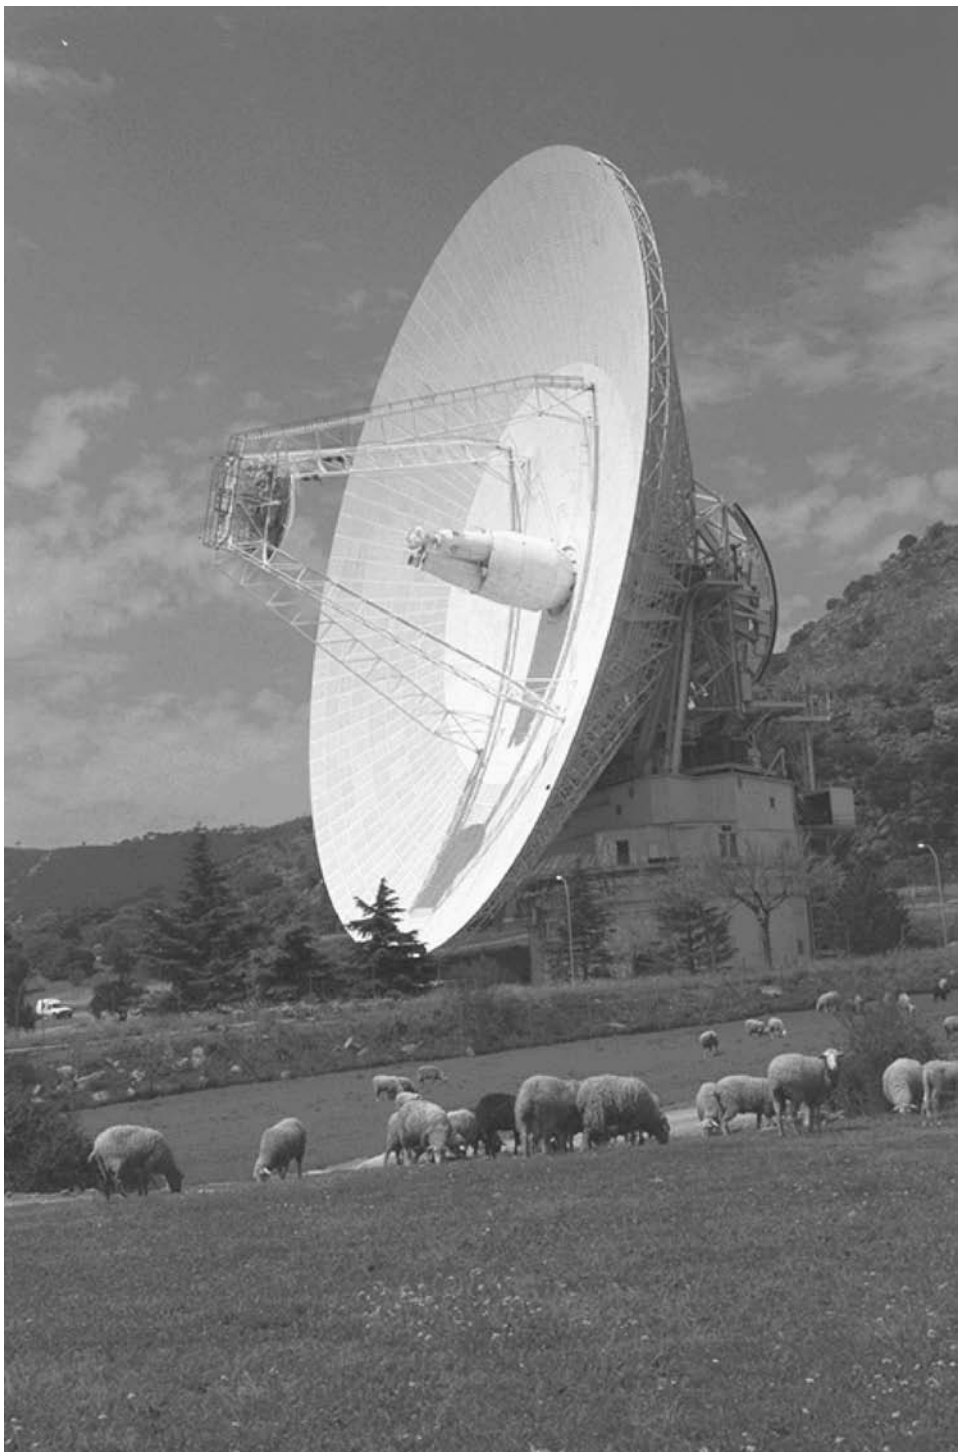

Fig. 2. 70-m antenna at Madrid Complex. (*Jet Propulsion Laboratory; California Institute of Technology; NASA, Pasadena, California*.)

25-meter (82-foot) antennas of the Very Large Array (VLA) in Socorro, New Mexico, operated by the National Radio Astronomy Observatory, and the Usuda 64-meter (210-foot) antenna operated by the Japanese Institute of space and Astronautical Sciences (ISAS).

Another advantage of arraying is that several smaller antennas can be combined to provide the same performance as a single large antenna. This was one of the key reasons for constructing three of the new 34-meter beam waveguide antennas at Goldstone. Following sophisticated software upgrades carried out in 2000, the four 34-meter (112-foot) antennas at Goldstone will be able to create the equivalent capability of a 70-meter antenna by 2001. Goldstone has long featured a 70-meter (230-foot) antenna; the 34-meter (112-foot) array will be available as backup in the event that significant downtime is needed on the 70-meter (230-foot) antenna, enabling the DSN to continue to meet its commitments.

Science

The DSN is a multifaceted science instrument used to improve knowledge of the solar system and the universe. It uses its large antennas and sensitive instruments to perform radio astronomy, radar, and radio science experiments. The antennas acquire information from signals emitted or reflected by natural celestial sources. Those data are compiled and analyzed by scientists in disciplines including astrophysics, radio astronomy, Earth physics, planetary radar, gravitation, and relativity.

Among many other science projects, the DSN provides the information needed to: help select landing sites for space missions; determine the composition of the atmospheres and surfaces of the planets and their moons; search for biogenic elements in the galaxy; study the star formation process; image asteroids; investigate comets, particularly their nuclei and

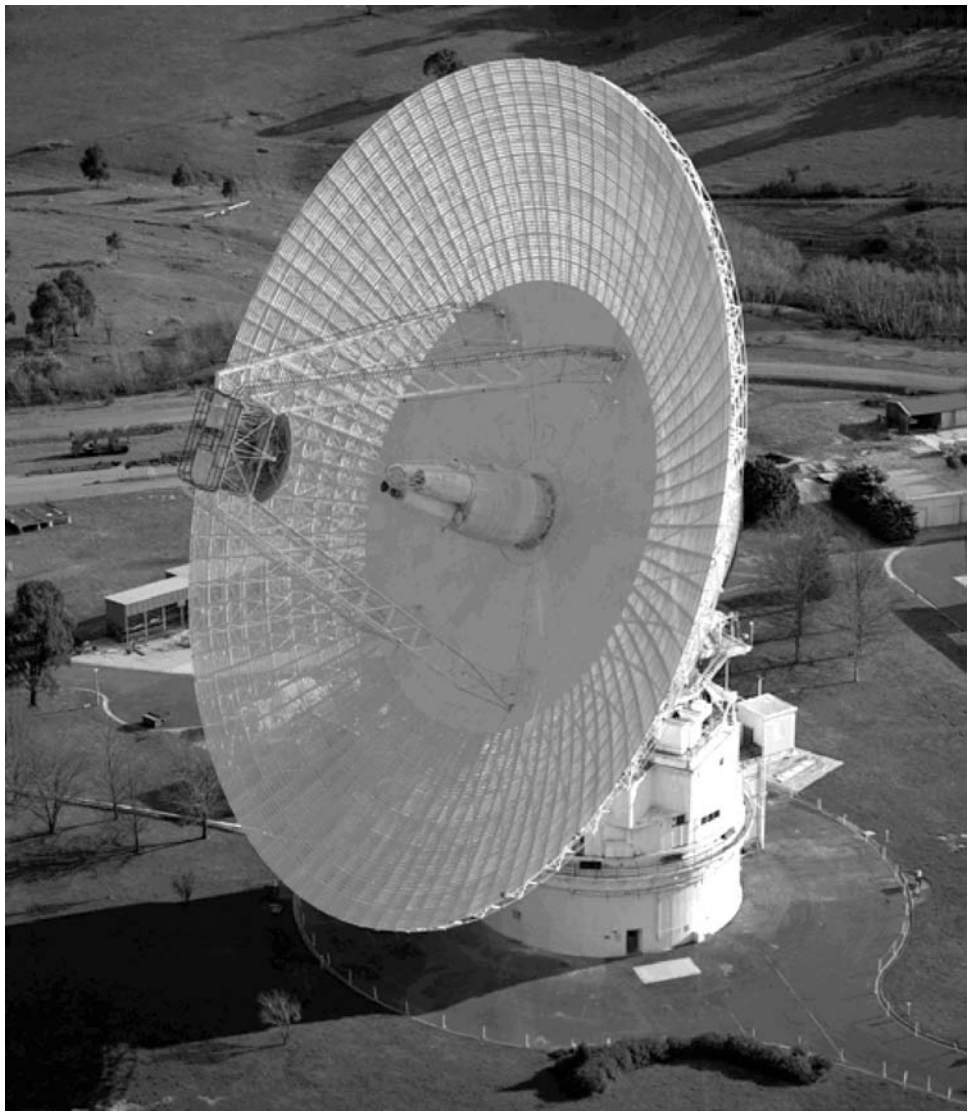

Fig. 3. View of the Canberra Complex showing the 70-m (230 ft) antenna. (*Jet Propulsion Laboratory; California Institute of Technology; NASA, Pasadena, California*.)

comas; search for ice on the moon and Mercury; and confirm the theory of general relativity.

The DSN radio science system performs experiments which allow scientists to characterize the atmospheres and ionospheres of planets, determine the compositions of planetary surfaces and rings, look through the solar corona, and determine the mass of planets, moons, and asteroids. It does this by precisely measuring small changes in the spacecraft signal as the radio waves are scattered, refracted, or absorbed by particles and gases near solar system objects.

The DSN makes its facilities available to qualified scientists as long as the research does not interfere with spacecraft mission support.

Astronomical Interferometry

An important DSN activity is radio interferometry, traditionally involving widely separated radio telescopes on Earth — but now taking an astronomical turn with the use of Earth-orbiting satellites as additional antennas out in space. Interferometry is a technique used by radio astronomers to electronically link radio telescopes so they work as if they were a single instrument with the resolving power of a single dish with a diameter equal to the separation between the individual dishes. Now a Very Long Base Interferometry space radio telescope has been taken into space for the first time. See also **Interferometer**.

NASA and the National Radio Astronomy Observatory joined with an international consortium of space agencies to support the launch of a Japanese satellite, creating the largest astronomical "instrument" ever built, a radio telescope more than two-and-one-half times the diameter of the Earth. This interferometry experiment was made possible by the February 1997 launch of the Very Long Base Interferometry Program satellite by Japan's ISAS. It approximately triples the resolving power previously available from ground-based telescopes — in fact, its resolving power is equivalent to being able to see a grain of rice in Tokyo from Los Angeles.

The DSN is using astronomical interferometry in cooperation with Japan to pursue such science objectives as the production of high-resolution maps of quasars and the search for high-brightness temperature components in compact extragalactic sources.

Teams

Gael Squibb is the director of JPL's Telecommunications and Mission Operations Directorate. Richard Coffin is deputy director. Richard B. Miller is manager for plans and commitments. Joseph Wackley is manager for operations. Joseph Statman is engineering manager, John Lesh is technology manager, and Wallace Tai is manager for systems engineering and standards.

DEEP VEIN THROMBOSIS AND PULMONARY EMBOLUS. Deep-vein thrombosis (also known as deep-venous thrombosis or DVT, sometimes called "phlebitis" or "thrombophlebitis") is the formation of a blood clot within a deep vein. It commonly affects the leg veins, such as the femoral vein or the popliteal vein or the deep veins of the pelvis. Occasionally the veins of the arm are affected (known as *Paget-Schrötter disease*).

If a clot in a vein breaks off and travels through your bloodstream, it can lodge in your lung. This is called *pulmonary embolism*, which is a very serious condition that can cause death. Blood clots in the thigh are usually more likely to break off and cause pulmonary embolism than clots in the lower leg or other parts of the body.

A blood clot also can occur in veins that are close to the surface of the skin. This type of blood clot is called *superficial venous thrombosis* or *phlebitis*. Blood clots in superficial veins are not dangerous because they can't travel to the lungs.

Many factors may increase your risk for deep vein thrombosis:

- Having an inherited blood clotting disorder
- Having slowed blood flow — resulting from injury, surgery, or immobilization — in a deep vein
- Having cancer and undergoing treatment for it
- Having other medical conditions, such as varicose veins
- Sitting for a long period of time, for example, on a long trip in a car or on an airplane
- Pregnancy, especially the first 6 weeks after giving birth
- Being over age 60 (although deep vein thrombosis can occur in any age group)
- Being overweight
- Taking birth control pills or hormone therapy, including for postmenopausal symptoms
- Having a central venous catheter, which accounts for almost 1 in 10 cases

Your risk for deep vein clots increases if you have several risk factors at the same time. For example, a woman with an inherited condition for clotting who also takes birth control pills has an even higher risk to have a blood clot.

The incidence of DVT, in the USA is about 159 cases per 100,000 individuals or about 398,000 cases per year. A definable etiology (reason) can be found in 80% to 90% of patients; this allows effective therapy to be delivered and allows for the other advantages of defining the blood coagulation protein or platelet defects, mentioned above, to be instituted. For example, about 28% of these patients will have antiphospholipid syndrome, and if treated with oral anticoagulants (coumadin), about 65% will fail (re-thrombose). Also, about 30%–50% of these patients will have coagulation protein or platelet defects which are hereditary; thus family members should be assessed and treated, when indicated, before a catastrophic event happens and obviously, effective and appropriate antithrombotic therapy for the afflicted patient should be long-term, not 6 weeks to 3 months.

The overall incidence of PE in the USA is about 139 cases per 100,000 individuals or about 347,000 cases per year (clinical data); the incidence of fatal PE in the USA is 94 per 100,000 individuals or about 235,000 deaths (autopsy data). The same scenario as that for DVT prevails for PE, about 80%–90% have a definable cause. If the PE is not fatal, every attempt should be made to define the blood coagulation protein or platelet defect responsible so the event can be treated with specific therapy, depending upon the underlying cause, thus saving the individual another, sometimes fatal, event.

Signs and Symptoms

It is important to see a doctor right away if you have symptoms of deep vein thrombosis or pulmonary embolism. Deep vein thrombosis can cause very serious complications if not treated.

Deep Vein Thrombosis. Only about half of the people with deep vein thrombosis have symptoms. The symptoms may include:

- Swollen area of the leg.
- Pain or tenderness in the leg. The pain is usually in one leg and may be felt only when standing or walking.
- Increased warmth in the area of the leg that is swollen or in pain.
- Red or discolored skin.

Pulmonary Embolism. Some people find out that they have deep vein thrombosis only after the clot has moved from the leg and traveled to the lung (pulmonary embolism). The symptoms may include:

- Chest pain when you take a deep breath
- Shortness of breath

Diagnosis

Commonly Used Tests. *Duplex ultrasound* is the most commonly used test to diagnose deep vein clots. It uses sound waves to evaluate the flow of blood in your veins. A gel is put on the skin of the leg. A handheld device is placed on the leg and passed back and forth over the affected area. This device sends sound waves from the leg to an ultrasound machine. A computer then turns the sound waves into a picture. The picture is displayed on a TV screen where your doctor can see the blood flow in your leg.

Venography may be performed if the duplex ultrasound does not provide a clear diagnosis. A venogram is an x ray used to examine veins. A dye is injected into a vein and then an x ray is taken of the leg. The dye makes the vein visible on the x ray. If the blood flow in the vein is slowed, it will show on the x ray.

Less Frequently Used Tests. *Magnetic resonance imaging (MRI)* shows pictures of organs and structures inside the body. MRI uses radio waves to make the image. In many cases, MRI can provide information that would not show up on an x ray. This test is being used more frequently to diagnose deep vein thrombosis. See also **Magnetic Resonance Imaging (MRI)**.

Computed tomography scan is a special type of X-Ray that can provide pictures of structures inside the body. This test is rarely used to diagnose deep vein thrombosis.

If an inherited blood clotting disorder is suspected, tests may be run for it. The presence of an inherited clotting disorder is suggested by:

- Repeated blood clots that can't be linked to any other cause
- Development of a blood clot in a vein at an unusual location, such as a vein in the liver, kidney, or brain

Treatments

The main goals in treating deep vein thrombosis are to:

- Stop the clot from getting bigger
- Prevent the clot from breaking off in your vein and moving to your lungs
- Reduce your chance of having another blood clot

Medicines. Several types of medicine may be used to treat and/or prevent deep vein thrombosis:

1. Anticoagulants decrease your blood's ability to clot. They are also known as blood thinners. They are used to stop clots from forming in people who are at risk for clots and to stop already formed clots from getting bigger. They do not break up blood clots that have already formed. (The body itself dissolves most clots over time.) See also **Anticoagulants**.
   Anticoagulants can be taken as either a pill (warfarin) or an injection (heparin).
   Your doctor may treat you with both heparin and warfarin (Coumadin) at the same time. Heparin acts quickly. Warfarin takes 2 to 3 days before it starts to work. Once the warfarin starts to work, the heparin is stopped.
   Pregnant women can't take warfarin and are treated with heparin only.
   Treatment for deep vein thrombosis with anticoagulants usually lasts from 3 to 6 months. However, the following situations may change the length of treatment: If your blood clot occurred after a short-term risk (for example, surgery), your treatment may be shorter;
   If you have had clots before, you will need longer treatment; and
   If you have certain other illnesses, such as cancer, you may need to take anticoagulants for as long as the illness is present.
   The most common side effect of anticoagulants is bleeding. You should call your doctor right away if you are taking warfarin or heparin and have easy bruising or bleeding. Blood tests can check how well the medicine is working.
2. Thrombolytics are medicines given to quickly dissolve a blood clot. They are used to treat large clots that cause severe symptoms. Because thrombolytics can cause sudden bleeding, they are used only in life-threatening situations.
3. Thrombin inhibitors are medicines that interfere with the clotting process. They are used to treat some types of clots and for patients who can't take heparin.

Other Treatments

Vena cava filters are used when you cannot take medicines to thin your blood, or when you are taking blood thinners but continue to develop clots anyway. The filter is inserted inside a large vein called the vena cava. The filter catches clots that break off in a vein before they move through the bloodstream to the lungs (pulmonary embolism). The filter doesn't prevent new clots from developing.

Graduated compression stockings can reduce the chronic swelling that can occur after a blood clot has developed in a leg. The leg swelling is due to damage to the valves in the leg veins. Graduated compression stockings are worn on the legs from the arch of the foot to just above or below the knee. These stockings are tight at the ankle and become looser as they go up the leg. This causes a gentle compression (or pressure) up the leg. The pressure keeps blood from pooling and clotting.

Some drawbacks of wearing the stockings are; they can be uncomfortable when worn all day; they can be hot; and They may be difficult to put on, especially for older adults and overweight people.

See also **Thrombosis**.

National Institutes of Health (NIH), Bethesda, MD

DEER FLY *(Insecta, Diptera)*. Small horse flies with banded wings; they are abundant in the eastern woods. In the west the name is applied to snipe flies. All species are annoying to humans.

DEER *(Mammalia, Artiodactyla)*. The deer (*Cervines*) comprise one of the larger groups of the order *Artiodactyla* (even-toed hoofed mammals). The various species of deer represent one of the most widely distributed of mammals throughout the world and appear in most locations with the exception of Australia, New Zealand, and central and southern Africa. These animals, however, have been introduced into Australia and New Zealand. Some species, notably those known as the true deer (*Cervinae*), are widely distributed. Others are found only in certain regions. It is notable, for example, that most of the deer found in South America are species indigenous to that continent and that these species are not found on other continents.

Generalizations are difficult because there are so many varieties. The male deer is called the stag or buck; the female is the hind or doe, and the young are called fawns. The males of most species of deer possess antlers, which are shed each year. Antlers project from the animal's frontal bone and their growth is fast, aided by lime and phosphorus in the diet. New antlers are made of a pliable bony material, covered with soft velvety skin and fine hair. The antlers soon branch, patterns varying with different species. The antlers are shed after the mating season. The process is hastened by the animal rubbing the antlers against a tree to accelerate ossification at the base of the antlers. The first antlers grown by a deer are small, but each year the growth becomes larger. The size and quality of the antlers decrease after a buck has passed the prime of his sexual life. The antlers are a major weapon of defense — as well as offense during the mating season.

The deer has short fur, red-brown to gray in color, usually white below. Fawns have white spots on their back and flanks until they are about 6 months old. Upon reaching 1 year, the young deer is graceful, alert, and very fast, attaining speeds as much as 50 miles per hour.

The general organization of the subfamilies making up the *Cervines* is given in Table 1.

The musk-deer is a small animal of the Himalayas and stands only about 20 inches high. In this particular species, antlers are lacking and the upper

	Key Deer		

jaw bears a pair of tusks, which may project several inches in the males. A related species, *M. sifanicus*, occurs in the northwestern part of the People's Republic of China. The limbs of the musk deer are long, ears are large, the coat is gray-brown, coarse, brittle, and long. The animal takes shelter in thickets of rhododendron, juniper, and birch where available. The diet is comprised of moss, leaves, and grasses. The animal is shy and is mostly active at night. The male musk deer possesses a small sac underneath the stomach which contains a dark brown, viscous substance that at one time was highly valued as a fixative for perfumes; the material is still one of the most effective for this purpose. Because of the number of animals taken for this material, the population has been threatened for a number of years.

The muntjacs are shy, small animals of several species. They also are known as barking deer for the sounds they can emit. They stand only about 2 feet high and have small two-tined antlers somewhat like those of the American pronghorn. The common Indian species, *C. muntjac*, is called the kakar. Their coloration is any one of several shades of brown.

There are about twelve species of the true deer. They are common and range widely over the earth, with exceptions as mentioned earlier. The Père David's deer is quite rare, numbering only a few hundred, all in zoological gardens or special preserves. It is not known in the wild state, but was discovered by a missionary in China in the mid-1800s in a herd of semidomesticated animals maintained by the Chinese Emperor near Peking. Fallow deer are small and highly preferred for display in parks and zoological gardens. The coloring is orange-red-brown with white spots. As indicated by Table 1, it is found only in the Middle East.

Of the Axis deer, the chital is known as the Indian spotted deer, is of medium size, with a reddish color and deep markings of white spots. The male's antlers are three tined. The animal lives in herds in the jungles of India, Sri Lanka, and Southeast Asia. The other axis deer is the hog deer, which lives in eastern Asia. The animal is pale brown featuring white spots. It assumes a darker brown coloration during winter.

Several species of the red deer are widely distributed, and it is one of the more common deer in many parts of the world. These deer inhabit woodland areas, but are known to migrate seasonally between mountain pastures in summer and lower valleys in winter. Although the red deer belong to a single genus, there are dozens of races with a vast variety of names applied to them, the names usually bearing some localized significance. With all of these complications, there is about only a dozen species importantly recognized. The so-called real red deer (*Cervus elaphus*) is found in northerly latitudes of Europe, ranging from the British Isles eastward to eastern Siberia. They also are found in North Africa, in the Middle East to Afghanistan, north of the Himalayas to and including the mountainous region of Tien Shan. In Europe and Russia, these deer are sometimes misleadingly termed *wapiti* (to be described later). Special names for these deer, depending upon location, include: maral (Caspian region); hangul (Kashmir); and shou (Tibet).

In North America, the species (*C. canadensis*) is the wapiti, or more commonly termed by Americans as the American elk, or simply the elk. This terminology also is somewhat confusing, particularly to Europeans, because the term *elk* was originally the common name for the moose in the Old World. The American elks or wapitis, whichever term one prefers, once were wide ranging over the northern regions of North America. They are now essentially limited to wilderness or parkland areas in the Rocky Mountains. Where protected, the elk multiplies rapidly and thus can be periodically harvested under official control. The elk competes with the white-tailed deer and mountain sheep for range. The bull elk is known for its bugling or loud, shrill call when challenging another bull. Hunters prize the head and antlers of the elk as trophies. An antler may measure some 6 feet, with six pointed tines per antler. The elk is about 10 feet (3 meters) long, 5 feet (1.5 meters), tall, and weighs up to 1,000 pounds (454 kilograms).

As indicated by Table 1, there are several other species of red deer.

The hollow-toothed deer are exclusive to the Western Hemisphere. With the exception of the white-tailed deer and its close relatives, the other species of hollow-toothed deer are found in South America. The white-tailed deer ranges in southern Canada as well as in the eastern and central United States, and southward into Central and South America. Weighing up to 200 pounds (91 kilograms), the white-tailed deer measures up to a length of 40 inches (102 centimeters) and height of just under 3 feet (0.9 meter). Exceptional specimens may weigh up to 350 pounds (159 kilograms). This is a valued sporting deer and the flesh is considered quite good. The deer gets its name because the underside of the tail is white as snow.

The mule deer is also common in western Canada and the United States. Its name is derived from its large ears, which resemble those of a mule. These animals prefer the forests and are a highly regarded sporting deer where found. They are about the same height as the white-tailed deer, but weigh less, a large buck usually not weighing over 200 pounds (91 kilograms). The Key deer is found on the islands off Florida, and essentially is a dwarf white-tailed deer. These animals seldom weigh over 50 pounds (23 kilograms).

The marsh deer, pampas deer, guemals, brockets, and pudus are all inhabitants of South America. The marsh deer is well named because it prefers the swamps and rivers of low country. It is widely hunted for meat and hide. The pampas deer is named for its habitat, the southern savannas and pampas of the southern regions of Argentina, Brazil, Paraguay, and Uruguay. The animal is small and reddish in coloration. It is well known for its speed and jumping ability. Large bucks may weigh up to 250 pounds (113 kilograms). The guemals sometimes are called "horse-camels" and are found in the high Andes. The brockets are delicate, small deer and, in South America, are reminiscent of the duikers of Africa. Their main habitat is the Amazon River basin. Unlike most South American deer, which feed at dawn and dusk, the brockets are nocturnal feeders, hiding and sleeping through most of the day. The smallest of all deer is the pudus, about the size of a small terrier dog. They range in the temperature forest zone of the Andes. The small antlers are in the form of spikes. There are records of the pudus being domesticated much as a dog.

The moose is a large deer with a broad muzzle, prehensile upper lip, and high shoulders. The male has broad palmate antlers. The moose is one of the largest of the deer, weighing a half-ton or more. They are some 6 feet (1.8 meters) tall and attain a length of about 9 feet (2.7 meters). Two species occur in North America, one ranging over the northern United States and Canada; the other species is in Alaska. The European species of moose, closely related to the common North American species, is locally called the elk.

As do other reindeer, the Eurasian reindeer has antlers in both sexes, set well back on the head and palmately branched at the tips. These animals are important in Lapland and in other northern parts of the Old World where they have been domesticated. One record indicates that one of these small deer pulled two men in a sled for a total of 16 hours at an average speed of 18 miles (29 kilometers) per hour. The meat and skin are excellent. At one time, the Lapps relied almost entirely on this animal for their livelihood. The milk of these small deer is rich and thick and must be diluted before drinking. From it are made cheese and other products, including an alcoholic drink.

There also have been problems of nomenclature involving reindeer and caribous. The terms essentially can be used interchangeably. The two North American species of caribou and several other species of deer are closely related to the true reindeer. The caribou (*R. arcticus*) is found from Greenland westward to Alaska. These animals travel southward to northern Canadian forests to spend the winters. In the spring, as snow conditions permit, they migrate north. The animal measures about 4 feet (1.2 meters) in height and the males weigh up to 700 pounds (318 kilograms). Although the Eskimos and American Indians did not domesticate caribou as in Lapland, the animal nevertheless has been extremely important to the livelihood of these people. The three species-complexes of caribou include the barren ground caribou, the woodland caribou, and the mountain caribou, their names essentially indicating their habitat. There are wide variations in coloration and other features of these animals. The woodland caribou is one of the largest of the caribous and is of the darkest color. The animal has very keen senses and consequently is difficult to stalk. It is believed that these animals, which are found from Alaska through northern Canada to the northern parts of Maine, originally came from Siberia. At one time, the animals were threatened with extinction, but during the last several years have been protected by law. The mountain caribou is the largest species, rich dark brown in coloration, and is found in British Columbia and Alberta.

The water deer is a small animal found along the margins of the Yangtse Kiang River in the People's Republic of China. The male has long curved tusks in the upper jaw and neither sex has antlers. The species is remarkable among deer, in that it produces from 3 to 6 young at a time.

Roe deer represent a small species, but a rather large population. They prefer a woodland habitat. The antlers of the male reach a little more than a foot in length, and in normal specimens have only three tines. These have been favorite hunting deer for hundreds of years and probably are the best known deer to Europeans. They are found all across Europe, from the British Isles eastward to Siberia and southward to the Caucasus, as well as in central Asia. Pockets of roe deer are found in the woodland areas that separate the highly industrialized communities of Europe.

The mouse deer, so-called because of its deer-like appearance, is not a deer, but is a traguline. See also **Tragulines**.

DEFERVESCENCE. A medical term indicating the decline of fever to a normal body temperature.

DEFICIENCY DISEASE. A disease due primarily to lack of certain nutritional substances considered essential to normal body function. These include various vitamins, minerals, such as iron, calcium, phosphorus, proteins and amino acids. Diseases of this type common at one time throughout the world were beriberi, scurvy, pellagra, and rickets. During the 20th century, with a knowledge of their causation and the greater availability of dietary supplements and general dietary knowledge, these diseases no longer are commonplace. See **Diet**; and **Vitamin**. Chemical elements important to the animal body are also described in several entries under the germane element.

However, in the case of protein deficiency, the recognition and importance of such protein-calorie malnutrition (PCM) diseases as kwashiorkor and marasmus have been given proper attention only during the past few decades. These diseases are described in the entry on **Protein**. Protein imbalance in the diet of the infant can also result in PCM-plus syndrome or infantile obesity. This condition is also described in the entry on **Protein**. PCM diseases are encountered most commonly in the underdeveloped countries of Africa, Asia, and Central and South America.

DEFLAGRATION. See **Explosive**.

DEFLATION. In geology, deflation is the action of the wind in removing unconsolidated fine-grained sediments from a land surface. In 1895 dust fell in Missouri which must have come entirely from western Kansas and Nebraska, since the intervening country was covered with ice and snow. Dust from the Sahara has been blown over Germany and England (transported by air 2000 miles; 3218 kilometers).

DEFLECTION ANGLE. In surveying, the angle between a line and the extension of the preceding line is called a deflection angle. See Fig. 1. When the survey is a closed traverse the algebraic sum of the deflection angles must equal 360 degrees. Circular curves are frequently laid out by the method of deflection angles, as illustrated in Fig. 2. Before it is possible to lay out points on the curve it is necessary to locate the P.C., P.I., and P.T. and obtain the central angle Δ which is numerically equal to the deflection angle Δ_1. Having the value of Δ_1, the deflection angles d_1, d_2, etc., may be calculated from the assumed chord lengths c_1, c_2, etc. The *transit* is first set up over the P.C. and sighted on the P.I. The deflection angle d_1, which gives the direction of the line from P.C. to x, is then turned off by means of the transit. The chord length c_1 is next measured on the ground by a steel tape which definitely fixes the positions of point x. Point y may be located by turning off the deflection angle d_2, and measuring the chord c_2 from the point x. Other points on the curve may be set in a similar manner. From the geometry of the figure it can be seen that the deflection angle (d_4) to the P.T. is equal to one-half of the central angle.

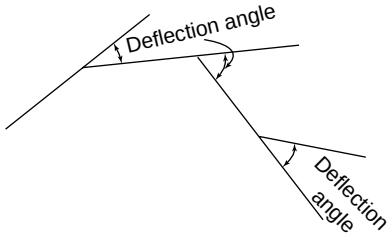

Fig. 1. Representation of deflection angle.

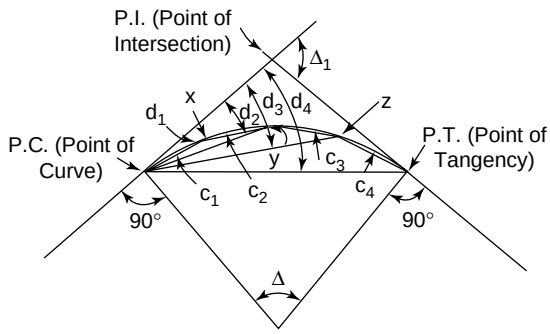

Fig. 2. Application of deflection angles to layout of circular curves.

DEFLECTION OF THE VERTICAL. The angular difference, at any place, between the direction of a plumb line (the vertical) and the perpendicular (the normal) to the reference spheroid. This difference seldom exceeds 30 seconds of arc. Also called station error. When measured at the earth's surface the deflection of the vertical is equal to the angle between the geoid and the reference spheroid.

DEFLECTION (Structural). Loads acting on a structure cause displacement of the structure relative to its original position. This is known as deflection. Deflection is characteristic of all structures since all materials are elastic to a certain extent. Figure 1 represents a beam that has been bent by the action of an external load. The deflections are the ordinates between the original and final positions of the elastic curve. The amount of deflection depends upon the load, stiffness of the material and the dimensions of the beam. The stresses cause the top fibers to compress and the bottom fibers to elongate. Since Hooke's Law states that stress is proportional to strain (deformation) as long as the stress is below the proportional limit, the stress in the beam due to bending will be proportional to the deformation of the fibers. The beam will come to rest or be in a state of equilibrium after the application of a load, when at every section the moment of the internal stresses equals the moment due to the external load.

Deflection is an important element in the design of a load-carrying structure. If strength is the limiting condition for which a beam is designed, the design should be tested for deflection to make certain that the displacements are within allowable limits. Deflection rather than strength often governs the design. This is especially true in the design of beams for buildings, where small deflections only, are permissible, because of the tendency of the deflection of the beams to crack terrazzo floors, plastered ceilings, etc. Solid rib and trussed bridges are also subject to deflection. Large steel bridges and building trusses are always cambered (see **Camber**) to counteract the effect of deflections. The deflections of beams, rigid frames, arches, trusses and other structures can be obtained by the methods of structural mechanics, both analytical and graphical.

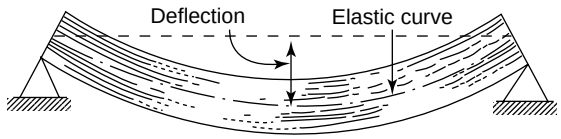

Fig. 1. Deflection of a bent beam.

Relative deflections under certain assumed conditions and loadings are determined in order to analyze statically indeterminate structures.

Maxwell's Law of Reciprocal Deflections, which may be applied to any loaded structure, states that the deflection of a point A in an arbitrary direction AC due to any load P applied at B in a direction BD is equal to the deflection of B in the direction BD when the load P is applied at A in the direction AC. See Fig. 2.

See also **Beam (Structural)**; and **Elasticity**.

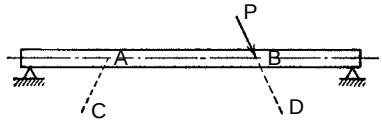

Fig. 2. Application of Maxwell's law of reciprocal deflections.

DEFLECTION YOKE. One or more electromagnets placed around the neck of an electron-beam tube for the purpose of producing a magnetic field to deflect one or more electron beams. Also simply termed a *yoke*.

DEFLECTOR. A plate, baffle, or the like that diverts something in its movement or flow, as: (a) a plate that projects into the airstream on the underside of an airfoil to divert the airflow, as into a slot — sometimes distinguished from a spoiler; (b) a cone-like device placed or fastened beneath a rocket launched from the vertical position, to deflect the exhaust gases to the sides; (c) any of several different devices used on jet engines to reverse or divert the exhaust gases; (d) a baffle or the like to deflect and mingle fluids prior to combustion.

DEFLUORIDATION. Defluoridation refers to methods of water treatment that reduce the concentration of fluoride in the water, normally in order to make it safe for human consumption. Some water treatments that have the capacity of reducing the fluoride concentration along with most other anions, or anions and cations, in the water are not considered defluoridation methods. Thus, general demineralizing methods like distillation, reverse osmosis, electrodialysis, and resin deanionization, which are able to remove fluoride fully or partly from the water, are not considered defluoridation methods. On the other hand, methods that only remove fluoride without any addition or reduction of other parameters are not yet discovered, which is why the expression "fluoride removal" lacks precision. Defluoridation is used to characterize methods that reduce the fluoride ion specifically, without other ***major*** changes to the quality of the treated water.

Objectives and Effects

The objective of defluoridation is to prevent or to mitigate *endemic fluorosis*. The term endemic fluorosis covers a wide variety of clinical manifestations of accumulative fluoride poisoning, mainly because of long-term consumption of relatively high concentration fluoride water. In mild cases, fluorosis is observed as a more or less repulsive mottling of teeth, *dental fluorosis*. More severe cases are known as *skeletal fluorosis*,

including deformities like knock knees (genu varum), bowleg (genu valgum), antero-posterior bowing of tibia, humpback (kyphosis), exostosis, and others.

Also, *nonskeletal fluorosis* includes swollen joints, muscular tenderness, rheumatism-like pain especially in the joints, systematic rigidity, stiffness, and impaired movement, all symptoms that give a feeling of rapid aging. Also, gastric problems, burning sensation during urination, mental retardation, and paraplegia are reported as clinical manifestation of fluorosis.

Safe Concentrations

According to the World Health Organization (WHO), the "optimum" and the maximum water concentrations are 0.8 and 1.5 mgF/L, respectively. These guidelines are adopted on the background of studies carried out mainly in low fluoride areas and in the decades before the widespread fluoridation of toothpaste. Presently, in a fluorotic area, most professionals consider 0.5 and 1.0 mg/L as the desired and maximum allowable concentrations, respectively. In a defluoridation process, the aim is to treat down to 0.5 mg/L, whereas 1 or 1.5 mg/L can be tolerated as the saturation level. Experience, as well as mass balances, show that once the drinking and cooking water is within these limits, the users do not need to worry about the daily intake of fluoride from other sources like food and normal use of toothpaste, even when residing in a fluorotic area.

Occurrence

Fluoride occurs in all natural waters. Ocean waters contain about 1 mg/L, whereas most fresh surface and subsurface waters contain less than 0.5 mg/L. Groundwater is, in general, subject to more variation at higher range. In fluorotic areas, groundwater and/or surface waters may contain up to 20–30 mg/L. As an extreme case, the concentration of 90 mg/L has been recorded in one Rift Valley Lake, where the water is soft but alkaline and the evaporation is high. Fluoride-rich waters that are subject to defluoridation for human consumption are in the range 1.5–20 mg/L.

Technology

Defluoridation differs from most other water treatments in four main aspects:

First, because fluoride does not deteriorate the piped water quality technically or oganoleptically, it is normally only required for the small part of the water that is used for drinking and cooking.

Second, defluoridation of large quantities of water, out of which only a small part is used for human consumption, is environmentally unsound, which is because of accumulation of correspondingly large quantities of toxic sludge that would create a new problem, more severe to deal with.

Third, most large cities and towns do not need defluoridation, because they are historically built in sites privileged to have good water resources.

Fourth, defluoridation is easily avoided in industrialized countries, as they have no difficulties in prospecting and transporting low fluoride water.

As a result of the above-mentioned four factors, defluoridation is often required in small scale and in rural areas in developing countries. As such, many defluoridation approaches have been launched, proclaiming success without unbiased field proof and thorough optimization. Further confusion comes with the fact that the process or the technical setup that may work in one context of socio-economic and environmental conditions may fail in another. Local availability and acceptability of the required materials, fluoride contamination level, and water quality are major factors to be considered when selecting the process and the design that minimizes the capital and running costs.

Treatment Processes

Defluoridation is carried out in one of three different processes:

1. A sorption process in a plug flow filter column with a medium that has a certain capacity of absorption, adsorption, or ion exchange of the fluoride. This process requires recharge or regeneration of the medium upon saturation. Numerous media are known to have defluoridation properties, see Table 1.

TABLE 1. SOME NATURAL MEDIA CAPABLE TO SORB FLUORIDE

Magnesite	Apophyllite	Natrolite
Stilbite	Clinoptilolite	Gibbsite
Goethite	Kaolinite	Halloysite
Bentonite	Verimiculite	Zeolite(s)
Serpentine	Alkalkine soil	Aiken soil
Acidic clay	Kaolinitic clay	China clay
Fuller's earth	Diatomaceous earth	Ando soil

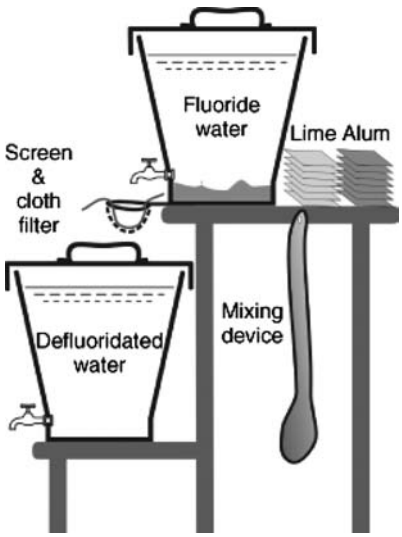

Fig. 1. The Nalgonda process as optimized for use in the Rift Valley.

2. A coprecipitation process in batch containers, where the precipitating chemicals are totally mixed with the raw water. This process requires filling of water and chemicals, mixing and settling, and subsequent withdrawal of the treated water and the produced sludge. In the so-called Nalgonda technique, a high dosage of alum and lime are used in a coagulation/sedimentation process, where the precipitation of aluminium hydroxide instantly binds a part of the water fluoride. A domestic approach for the Nalgonda process is given in Fig. 1.
3. Contact precipitation is a process where the water is mixed with the precipitating chemicals, calcium and phosphate ions, flowing into a catalytic filter column. So far, this process is only known to operate in a fluoride-saturated bone char, being the catalyst, dosed with calcium chloride and sodium dihydrogen phosphate. Contact precipitation is considered to be the process of choice in the future, when the local availability of bone/bone char reaches its limit.

Sorption Design

The sorption process may be designed on the basis of daily water demand, capacity of the medium, the raw water contamination level, proposed length of operation period, and the bulk density of the medium. The required column treatment capacity and the amount of medium required in a filter column are calculated (Eqs. 1 nd 2). From the bulk volume of the medium (Eq. 3), the dimensions of the column are derived (Eqs. 4 and 5):

$$\kappa = D \cdot P \tag{1}$$

$$M = \frac{D \cdot P \cdot (F_r - F_t)}{1000 \cdot C} \tag{2}$$

$$V_{\mathrm{m}} = \frac{M}{\sigma} \tag{3}$$

$$d = \sqrt{\frac{4000 \cdot V_{\mathrm{m}}}{\pi \cdot h}} \tag{4}$$

$$H = 1.2 \cdot h \tag{5}$$

where D = is daily water demand, L/day.
C = is capacity of the medium, g/kg.
F_r = is raw water contamination level, mgF/L.
F_t = is treated water concentration, (0.5) mgF/L.
P = is proposed length of operation period, days
σ = is bulk density of the medium, kg/L.
κ = is required column capacity, L.
M = is amount of medium required in a filter column, kg.
V_m = is bulk volume of the medium, L.
d = is inner diameter of the filter column, cm.
h = is height of medium in the column, cm.
H = is height of the column, cm.

Unfortunately, the capacity of the medium, and its purity, is subject to batch variation. Further, it depends on the fluoride concentration in the raw water. In practice, however, the capacities of 4, 1, and 0.03 g/kg are for good qualities of bone char, activated alumina, and activated clay, respectively.

Nalgonda Process Design

In the Nalgonda and similar processes, the container used has to have a volume well over the daily usage, which will allow for comfortable mixing in the container as well as include provision for the sludge water loss. A plastic bucket of 20 L is often sufficient for the daily use of a family. About 18 L can be treated at a time, out of which about 16 can be used.

The Nalgonda process design is complicated and must be confirmed empirically, which is mainly because of the coprecipitation that lacks stoichiometry, the great variation in media quality and solubility, and the efficiency being dependent on the raw water quality, in particular the fluoride concentration, pH, and the alkalinity. The best possible estimation is based on the Freundlich equation:

$$m = \frac{V_b \cdot (F_i - F_o)}{\alpha \cdot F_o^{1/\beta}} \tag{6}$$

where m = is amount of alum required for a daily treatment of a batch, in g.
F_r = is fluoride concentration in the raw water, in mg/L.
F_t = is residual fluoride concentration in the treated water, in mg/L.
V_b = is volume of water to be treated in batch, L.
α = is sorption capacity constant, $L^{(1-1/\beta)}\ mg^{2/\beta}g^{-1}$.
β = is sorption intensity constant.

Any resulting pH between 6.2 and 7.6 is adequate. For pH = 6.7 and required residual fluoride between 1 and 1.5 mg/L, $\alpha = 6$ and $\beta = 1.33$. The amount of lime required may be 20–50% of the alum dosage.

Alum and lime are added simultaneously to the raw water bucket where it is dissolved/suspended by stirring. The operator should stir fast while counting to 60, i.e., about 1 minute, and then slowly while counting to 300, i.e., about 5 minutes. The mixture is left for settling for about one hour. The treated water is then tapped through the cloth into the treated water bucket from where it is stored for daily drinking and cooking. This separation of the water from the sludge is essential in order to avoid escape of the toxic aluminium to the treated water and in order to avoid the detachment of removed fluoride from the aluminium hydroxide flocs during storage.

Testing

The coprecipitation technique, although arbitrary in nature, is reliable in the sense that the same removal is obtained if the procedure followed exactly.

On the other hand, the process results in poor removal efficiency, and it demands burdensome daily preparation.

The sorption process is less burdensome. It is also able to provide high removal efficiencies, even at high fluoride levels in the raw water. However, the operator has to watch for the break through the column at saturation. As fluoride is oganoleptically neutral, this cannot be done without either regular testing of the treated water fluoride or checking the accumulated water flow.

Testing the fluoride concentration in the treated water was impossible without expensive laboratory equipment. Now, simple, reliable, and cheap test kits are available.

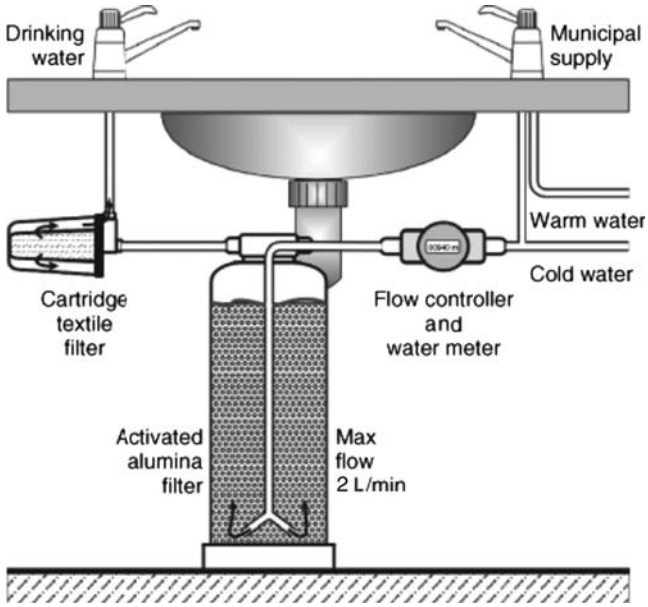

Fig. 2. A safe and user-friendly setup of defluoridation based on sorption, in case of activated alumin. The system, containing 8 kg AA, is commercially available in Scandinavia and declared to be able to treat 2000 L of water containing 5 mg/L.

Figure 2 shows a user-friendly setup for household defluoridation. The secondary cartridge filter ensures that no toxic aluminium can escape with the treated water, and the water meter ensures that accumulated water flow can be compared with declared capacity.

DEFOAMING AGENTS. Film breakers or defoaming agents are substances used to reduce foaming caused by proteins, gases, or nitrogenous materials which may interfere with processing or the desired characteristics of the end-products. Processes particularly prone to foaming conditions include the Kraft process for papermaking, where a very foamy pulp slurry is formed; phosphoric acid production from phosphate rock; beet sugar processing; several fermentation processes; and, in terms of the end-product, latex paints. See also **Paints and Coatings**.

The terms *defoamer* and *antifoam* or *antifoaming agent* are frequently used interchangeably. A *defoamer* best describes a substance that kills the foam from above, once it exists. An *antifoaming agent* stops the foam from forming in the first place. Often a defoamer will be a poor antifoaming agent, and vice versa. Defoaming agents, when used in small concentrations, can be quite effective. Where a suitable chemical substance cannot be found, physical means may be required. These may be mechanical, electrical, or thermal in nature. The mechanical devices are fundamentally simple, usually taking the form of rotating breaker arms. The presence of a hot surface near a foam tends to destroy the foam. Essentially, a portion of the foam is evaporated, causing the acceleration of its breakdown. It has also been established that electrical discharges tend to weaken or destroy films.

Mechanisms of Defoaming Agents. These agents may operate via a number of mechanisms, but the most common ones appear to be those of entry and/or spreading. The defoamer must first of all be insoluble in the foaming liquid for these mechanisms to function. Second, the surface tension of the defoamer must be as low as possible. The interfacial tension between defoamer and foamer should be low, but not so low that emulsification of the defoamer may occur. Third, the defoamer should be dispersible in the foaming liquid. It was first shown in 1948 that thermodynamically the entry of the defoamer droplet into a bubble surface occurs when the entering coefficient has a positive value. The physics of bubbles is described in entry on **Foam**.

A type of defoamer may consist of a dispersion in oil of fine particles of silica coated with silicone, the silicone surface of the particles causing them to be hydrophobic. The defoaming action of such a formulation can be explained on the basis of the entry mechanism. Hydrophobic particles can act as an emulsifying agent where the defoamer oil constitutes the continuous phase and the foam constitutes the dispersed phase. In experimental trials, it has been found that excessively hydrophobic particles, such as powdered Teflon, do not function as well as silicone-coated particles. An emulsifier particle must be wetted to some extent by the dispersed phase in order to function as an emulsifier.

The more efficient defoaming mechanism of spreading involves transport of underlying liquid so that the liquid is replaced by a film of defoamer that does not support foam. A drop of oleic acid added to water spreads at a velocity of 30 miles (48.2 kilometers) per hour. The mechanical shock to a film by such a defoamer may be considerable. In addition to the foam-destroying aspect, spreading is also of value as a defoamer-dispersion method, particularly in viscous or poorly stirred systems.

Defoaming agents are in three principal categories, but sometimes are used in combination: (1) surfactants made soluble, (2) dispersions of hard particles, and (3) dispersions of soft particles. The fatty acid-fatty alcohol combination in hydrocarbon oil is an example of a solubilized surfactant defoaming formulation. Paraffinic waxes and fatty amides may be used in soft-particle formulations. The most common of the hard-particle formulations is silica or a mineral coated with silicone dispersed in a vehicle. A particle size as small as 0.02 micrometer may be optimal.

Choice of defoaming agents in the food field is somewhat restricted because substances used obviously must be nontoxic and not produce off odors, off colors, or off tastes. Chemical defoaming agents commonly used in food processing include decanoic acid, dimethylpolysiloxane, lauric acid, mineral oil (white), myristic acid, octanoic acid, oleic acid, oxystearin, palmitic acid, petrolatum, petroleum wax (synthetic), silicon dioxide, sorbitan monostearate, and stearic acid. See also **Foam**.

An example from the brewing industry points out the importance of defoaming agents. Advantages of their use include: (1) higher production through increased fermentation capacity — up to 20% more throughout; (2) the lid of the fermentation tank can be left on, reducing oxidation and improving sanitation; (3) lower oxidation rate, which gives a better physical and chemical stability to the beer as the denatured or partially denatured protein levels remain low, and thus reducing turbidity; and (4) less yeast build-up on the sides of the tank, thus reducing cleaning requirements. Inasmuch as foam is a consideration in the final quality of the brewed product, effective foam control during processing can later affect the "head" of the final product, providing for a stable, long-lived, creamy foam. Thus, a defoaming agent for process use must be insoluble in the beer and capable of removal so that it does not detract from the head of the final product.

DEFOLIANT. See **Herbicide**.

DEFORESTATION. Those practices or processes that result in the change of forested lands to nonforest uses. This is often cited as one of the major causes of the enhanced greenhouse effect for two reasons: (1) the burning or decomposition of the wood releases carbon dioxide; and (2) trees that once removed carbon dioxide from the atmosphere in the process of photosynthesis are no longer present and contributing to carbon storage.

See also **Climate**; and **Global Warming**.

DEFORMATION BANDS. Bands formed inside the crystals of metals by plastic deformation in which the crystal lattice has been rotated into orientations differing from that of the rest of the crystal. See also **Crystal**.

DEFORMATION (Continuous, Mathematics). A transformation that shrinks, twists, etc., in any way without tearing. A continuous deformation of an object A into an object B is a continuous mapping $T(\rho)$ of A onto B for which there is a function $f(\rho, t)$ which is defined and continuous (simultaneously in ρ and t) for real numbers t with $0 \leq t \leq 1$ and points ρ of A and for which $F(\rho, 0)$ is the identity mappings of A onto A, $F(\rho, 0) \equiv \rho$, and $F(\rho, 1)$ is identical with $T(\rho)$. With this definition, a circle in the plane can be continuously deformed to a point although a circle around the outer circumference of a torus cannot be deformed continuously into a point, or into one of the small circles around the body of the torus, without leaving the torus; i.e., with all values of $F(\rho, t)$ being points on the torus. It is frequently required that a continuous deformation not bring points together; i.e., that the above function $F(\rho, t)$ be a one-to-one correspondence for each value of t. Then a circle in the plane can be continuously deformed into a disc (a circle and its interior), but not into a cylinder or a sphere. It is said that two mappings T_1 and T_2 of a topological space A into a topographical space B can be continuously deformed into each other if there is a function $F(x, t)$ which has values in B, which is continuous simultaneously in x and t for x in A and $0 \leq t \leq 1$, and for which $F(x, 0) \equiv T_1(x)$ and $F(x, 1) \equiv T_2(x)$ for each x of A. Two mappings are said to be homotopic if they can be continuously deformed into each other. If A is contained in B and T_1 is the identity mapping of A onto A, then T_2 is a continuous deformation (in the above sense) of A into the range of T_2 if T_1 can be continuously deformed into T_2.

See also **Mapping (Mathematics)**; and **Topological Space**.

DEFORMATION (Materials). The change in the shape of a body that accompanies a stressed condition is called deformation. The total amount of deformation in one direction is the total deformation. Unit deformation is the deformation per unit of length and is commonly called strain. Permanent deformation is known as set. If an axial load is applied to a body, the length and lateral (cross-sectional) dimensions are changed. Poisson's ratio is the ratio of lateral unit deformation to longitudinal unit deformation.

Deformation that is the result of a flexural stress (see **Flexure**) is called bending deformation. Shearing of shear deformation is caused by shearing stress.

DEGASIFICATION. Removal of gas, as applied particularly to the removal of the last traces of gas from wires used in vacuum apparatus, from metals to be plated, and from substances to be used in other specialized applications. Untreated glass always contains water, carbon dioxide, oxygen, and traces of other gases within it and on its surface, and these are ordinarily in a state of equilibrium with the surroundings. When the pressure is reduced, however, the equilibrium is upset, and these gases, being gradually released from solution in and adsorption on the glass, spoil the vacuum. It is usual to drive the gases out of the glass by baking the glass at a temperature of about 350°–500 °C, while on the vacuum pump. Degassing of metal is necessary for the same reason as in degassing of glass, but because of the larger quantities of gas present in metals, more complex methods of degassing must be employed. These include baking at high temperature, eddy-current heating, and electron bombardment. See also **Gettering**.

DEGENERACY. In the kinetic theory of gases, a gas that does not obey the ideal gas laws is referred to as a degenerate gas. The greater the deviation of the real gas from the ideal, the greater is its degeneracy.

A *degenerate electron gas* is an electron gas that is far below its Fermi temperature, that is, which must be described by the Fermi distribution. The essential characteristic of this state is that a very large proportion of the electrons completely fill the lower energy levels, and are unable to take part in any physical processes until excited out of these levels.

DEGENERATE STATE. In quantum mechanics, when different states of motion correspond to the same energy level, the states are said to be degenerate. The degeneracy can often be removed by the application of a perturbing field with the effective introduction of a new quantum condition, i.e., the breakup of one eigenvalue into several.

DE GRAAF, REGNIER (1641–1673). De Graaf's contributions to anatomy and physiology began in the early 1660s during his student days at the University of Leiden. An intensely competitive atmosphere prodded the search for new discoveries and new methods that could expose small anatomical structures. Delighted in the spectacle of colored fluids injected into vessels and organs, de Graaf shared in the development of such exploratory techniques. He also used the magnifying glass, but it plays a very small role in his published writings.

Hoping to bolster the theory of digestion proposed by Franciscus dele Boë Sylvius, his professor at Leiden, de Graaf also succeeded in obtaining pancreatic juice by inserting a feather quill attached to a small flask into the pancreatic duct of a living dog. He tested the juice, however, chiefly by simply tasting it.

Having begun medical practice in Delft, de Graaf published two celebrated treatises on the mammalian reproductive organs in 1668 and 1672. The first demonstrated that the testes were composed of minute vessels, and the second, on the female organs, made the case in its detailed text and plates that the ovaries, characterized since the days of the Hellenistic anatomists as female "testicles," were indeed ovaries. In the process, he described the development of the vesicles now known as the Graafian follicles, though he mistook them for the eggs themselves. After a notoriously bitter priority dispute with the microscopist Jan Swammerdam, a former friend and fellow student at Leiden, de Graaf died in 1673 at the age of 32.

DEGRADATION (Chemical). A gradual decomposition occurring in stages with well-marked intermediate products. For example, the maltose chain loses one carbon atom under certain conditions to produce a sugar with eleven carbon atoms in its skeleton. In fact, the term degradation often means specifically a reduction of the number of carbon atoms in an organic compound, usually an aliphatic compound. Among the specific methods used for this purpose are the Hoffmann reaction, treating an amide with a hypohalite; the conversion of fatty acids to methyl ketones, followed by oxidation; and the Curtius reaction for the conversion of an acid azide to the primary amine.

Kraft Method. A method of reducing the number of carbon atoms in the molecule of an acid, especially a fatty acid by the decomposition of its calcium or barium salt in the presence of a salt of acetic acid, followed by oxidation of the resulting methyl ketone:

$$(RCH_2COO)_2Ca + (CH_3COO)_2Ca \rightarrow \underset{\downarrow\ CrO_3}{2RCH_2COCH_3} + 2CaCO_3.$$
$$2RCOOH + 2\ CH_3COOH.$$

See also **Decomposition (Chemical)**.

DEGRADATION (Energy). The second law of thermodynamics is sometimes referred to as the Law of Degradation of Energy, because of the statement that the entropy of an isolated system is increased by irreversible processes involving energy changes, and that, therefore, the sum of the available energy tends to decrease.

DEGRADATION (Nuclear). In atomic physics, degradation means a loss of energy by collision. Neutron degradation is also called moderation.

DEGRADATION (Oxidative). See **Antioxidant**.

DEGREE DAYS. A form of accumulated temperature; a unit employed in heating and air-conditioning calculations. For specifying the nominal heating load in winter, there are as many degree days as there are degrees Fahrenheit difference in temperature between the mean temperature for the day and 65 °F (18.3 °C) (60 °F (15.6 °C) in Great Britain). For example, in a month during which the outside temperature averaged 20 °F (−6.7 °C) for 10 days and 35 °F (1.7 °C) for 20 days, there are 1050 degree days. This number is found thus: Degree days $= 10(65 - 20) + 20(65 - 35) = 1050$. One *heating degree day* is given for each degree that the daily mean temperature departs below the base of 65 °F (18.3 °C). In accumulating degree days over a "heating season," days on which the mean temperature exceeds 65 °F (18.3 °C) are ignored. The energy requirements for air conditioning or refrigeration are estimated by *cooling degree days*, one given for each degree that the daily mean temperature departs above the base of 75 °F (23.9 °C). As used by the U.S. Army Corps of Engineers, degree days are computed as departures above and below 32 °F (0 °C), positive if above, and negative if below. To avoid confusion, it might be well to call this a "freezing degree-day."

The period of time between the highest point and the succeeding lowest point on the time curve of cumulative degree days above and below 32 °F (0 °C) is called the *freezing season*; while the period of time between the lowest point and the succeeding highest point is called the *thawing season*. The *freezing index* is the number of degree days (above and below 32 °F; 0 °C) between the highest and lowest points on the cumulative degree-days time curve for one freezing season. The index determined for air temperatures at 4.5 feet (1.3 meters) above the ground is commonly designated as the "air freezing index"; while that determined for temperatures immediately below a surface is known as the "surface freezing index." See also **Climate**.

DEGREE (Electrical). This is $\frac{1}{360}$ of a cycle of alternating current representing one electrical revolution.

DEGREE (Geometry). A degree is the unit measured by the central angle subtended by $\frac{1}{360}$ of the arc of a circle. This unit of angular measurement has been extended to a great many practical uses, as, for example, the reading of compass bearings in degrees. A right angle contains 90°; a minute is $\frac{1}{60}$ of a degree, and a second is $\frac{1}{60}$ of a minute.

Degrees also are measured in *radians*. A radian may be defined as an angle which, if placed at the center of a circle, will intercept an arc of a length equal to the radius of the circle. The ratio of the circumference to the radius is identical for all circles. Thus, the radian has a fixed value, that is, it is a constant angle and independent of the size of the circle. The circumference of a circle is 2π times the radius. Thus, the circumference embraces 2π radians and the following relationships apply: 2π radians $= 360°$; π radians $= 180°$. One radian equals $180°/\pi$, or 57.29578 degrees. One degree equals 0.0174533 radian.

DEGREE RANKINE. See **Units and Standards**.

DEGREES OF FREEDOM (Statistics). The number of degrees of freedom in a statistical quantity is the number of independent values necessary to determine it. A sample of n values $x_1, x_2, \ldots, x_n$ has n degrees of freedom but the sum

$$\sum_{i=1}^{n}(x_i - \overline{x})^2$$

is regarded as having $n - 1$ because, for given x, only $n - 1$ values are assignable at will.

By extension, the number of degrees of freedom of a statistical distribution relates to the degrees of freedom of the distributed statistic. For example, χ^2 being the distribution of the sum

$$\sum_{i=1}^{n}(x_i - \overline{x})^2/\sigma^2$$

has $n - 1$ degrees; and the F-distribution, which concerns the ratio of two independent such quantities has a pair of degrees of freedom, one relating to the numerator and the other to the denominator of the ratio.

DEGREE (Thermal). In essence, the thermal degree represents molecular activity, in that temperature depends upon molecular velocity. There are several temperature scales, each of which is divided into measurement units. The key unit in each scale is a degree. The most common temperature scales are Celsius (Centigrade) and Fahrenheit. Thus, the terms degrees Celsius (°C); and degrees Fahrenheit (°F). See also **Temperature**.

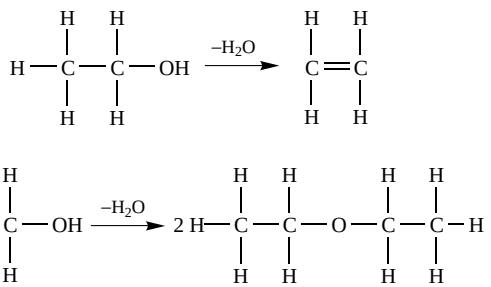
DEHISCENCE. The splitting open of a pod or anther, causing seeds to be ejected with explosive force. See also **Seed**.

DEHUMIDIFICATION. A process, used in air conditioning and in the process industries, in which air or other gases partially saturated with water are subjected: (1) to cooling below their dew point, so that part of the water vapor is condensed and thus separated from the gas; (2) to the action of chemical desiccants, either liquid or solid, which adsorb moisture from the gas; or (3) to a combination of both actions. The most commonly used gas in industry is compressed air. This air requires drying and conditioning for trouble-free operation of pneumatic equipment, including tools, instruments, and automatic controllers. In paint manufacture, dry

inert gas is used to blanket agitation operations. Dry process gases, such as nitrogen or hydrogen, are used in metal-annealing operations. The manufacture of some transistors requires blanketing with a dry gas during assembly.

Deliquescent dryers (dissolving desiccant types) and refrigeration-type dryers are adequate for most air-comfort applications and some industrial applications. Usually, these systems only partially remove moisture from air and other gases and generally require additional drying equipment. To meet tight drying specifications, a solid, regenerable desiccant that adsorbs the moisture usually is used. Desiccant regeneration usually is accomplished by the application of heat or purging, or a combination of both procedures. Normally, dual drying towers are used for continuous service, allowing one tower to be on-line, while the other tower is being regenerated. Desiccants most frequently used are silica gel, activated alumina, and molecular sieves. Desiccant systems permit efficient dew-point performance in the range of -40 to $-100\,^{\circ}$F (-40 to $-73\,^{\circ}$C) and are available in a wide range of capacities and pressure ratings (from atmospheric pressure up to 340 atmospheres; 5000 psig).

DEHYDRATION (Chemical). Removal of water from a substance or system or chemical compound; or removal of the elements of water, in correct proportion, from a chemical compound or compounds. The elements of water may be removed from a single molecule, or from more than one molecule, as in the dehydration of alcohol; this may yield ethylene, by loss of the elements of water from each molecule, or ethyl ether, by loss of the elements of water from two molecules, which then join to form a new compound:



Many reactions known in chemistry under special names, such as neutralization, esterification and etherification are dehydration reactions.

In the food processing field, dehydration is sometimes described as the removal of 95% or more of the water from a food substance, by exposure to thermal energy by various means. The aims of dehydration are reduction in volume of the product, increase in shelf life, and lower transportation costs, among other factors. There is no clearly defined line of demarcation between drying and dehydrating, the latter sometimes being considered as a supplement of drying. Usually, the direct use of solar energy, as in the drying of raisins, hay, etc., is not lumped in with dehydrating. The term dehydration also is not generally applied to situations where there is a loss of water as the result of evaporation. *Rehydration* or *reconstitution* is the restoration of a dehydrated food product to essentially its original edible condition by the simple addition of water, usually just prior to consumption or further processing. The distinction between the terms drying and dehydrating may be somewhat clarified by the fact that most substances can be dried beyond their capability of restoration. Important food products that are dehydrated include animal feedstuffs, hops, malt, oat, peanut (groundnut), potato, rice, and sweet potato. See also **Drying (Process)**.

DEHYDRATION (Physiological). A clinical state in which the body does not retain sufficient fluids to maintain the normal functions of blood circulation, excretion of waste products through the kidneys, temperature regulation, and individual cell performance. A common cause of dehydration is excessive loss of fluid through vomiting and diarrhea, frequently accompanying a disease such as intestinal flu (gastroenteritis). Infants exhibit little tolerance for prolonged dehydration and may readily go into coma, followed by death, if the underlying causes of the dehydration are not corrected immediately. Among treatments used to overcome dehydration are (1) use of anti-vomiting preparations, (2) administration of intravenous or subcutaneous fluids, and (3) application of liquids to the colon by enema, inasmuch as the colon readily absorbs fluids. These and other actions, with particular emphasis on clinical measurements as guidelines, comprise a system of body water and electrolyte system management.

In administering therapy, the fact that the body has made some adjustments to water deficiency must be kept in mind. Even though water has been lost from all compartments, the body, by manipulating solute, seems able to defend organs at particular risk, notably the brain. It appears that by retaining solute or increasing the solute content of the brain, the body protects the brain from suffering as much water loss as occurs in other organs. Thus, the brain does not necessarily shrink to the same extent that total body water diminishes, particularly if dehydration is gradual. It should be noted that if complete replacement of the deficit is made quickly, the brain may take up more water than it normally contains, leading to cerebral edema. A particular complication of therapy in infants is the onset of seizures. A result of acute dehydration can be permanent brain damage — apparently a consequence of cerebral hemorrhages induced in part by tearing of vessels as the shrinking brain pulls away from the calvaria.

The physiology and physical chemistry of body water are described in entries on **Water**; and in the section on "Water Deficiency" in the entry on **Kidney and Urinary Tract**. See also **Heat Stress (Physiological)**.

Normally, water enters the body via the gastrointestinal tract and remains in the body for about two weeks. About half of the water is taken in as liquid water; the other half as contained in solid foods. A little over 10% of the water present in the body results from oxidation processes. Where there are no dehydration processes present, water loss normally occurs as (1) liquid loss (60%) by way of urine and feces, about 94% of this via the urine, and (2) vapor loss (40%) by way of the lungs and skin, roughly in equal proportions. Even if all water intake stops, the processes of water loss continue, the body continuing to lose about 2% of its total weight per day as the result of continuing water loss.

Fluid Loss Replacement. Sixty percent of body weight is made up of water. Although the body does not contain reservoirs per se that are filled with water, all of the cells that make up muscles, tissues, bones, vessels, and even blood are composed chiefly of water. Water provides the medium by which nutrients are transported. The body depends upon a daily fluid intake that is balanced against the amount lost from sweating, perspiration, waste elimination, and exhalation of moist air from the lungs. Normally, an adult consumes about 2.5 quarts (liters) or roughly 10 cups of water a day to replace fluid losses. Not all is in the form of water. There is considerable water in foods. A simple way to gage fluid loss is to weigh the body before and after exercise or physical work at the beginning or end of each day. For each pound lost, 2 cups of fluid should be consumed to replace the lost water. For athletes in competitive endurance events, water intake becomes even more important, and added attention should be given to drinking 3 to 6 ounces of cool fluids at refrigerator temperature ($41\,^{\circ}$F ($5\,^{\circ}$C)) every 10 to 15 minutes. The cooler temperature allows faster gastric (stomach) emptying, which in turn permits the fluid to enter the bloodstream faster. Because the thirst mechanism is not a reliable indicator of the need to replace fluids, it is necessary to drink as much fluid that is tolerable, preferably through regular and timely consumption.

Water is the most important fluid that an athlete can consume. So-called *sports drinks* are popular, but it should be recalled that 97% of these drinks are water. Research has indicated some value in consuming drinks that contain a small amount of glucose (about 2.5%) and traces of electrolytes that help replace losses and provide another source of energy. Such drinks may be particularly helpful for long endurance events, such as marathons, in which most of the body's glucose is consumed after 90 minutes of exercise.

In some very strenuous exercise (wrestling, etc.), the fluid loss from the skin and respiratory surfaces can average 2 quarts (liters) per hour. Replacement of lost fluids, particularly during hot weather, is vital to preventing hyperthermia (overheating) and to avoid excessive fatigue.

Undiluted carbonated beverages and caffeine- and alcohol-containing beverages, including beer, are not recommended by physicians for fluid replacement during or immediately following exercise. Carbonated drinks make the individual feel "too full" and caffeine and alcohol are diuretics.

In addition to serving as a quick energy source, carbohydrate-containing beverages promote rapid fluid absorption in the stomach. There is debate about the best source and concentration of carbohydrate for this purpose.

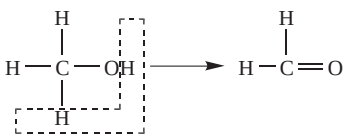
Dilute fruit juices are widely recommended, as are some of the commercial preparations.

Electrolytes are ionized mineral elements and salts vital to normal body functioning. Electrolytes are necessary for development of electrical potentials across cell membranes, thus affecting muscle contraction and nerve conduction. Each electrolyte has specific functions. Sodium regulates body fluid volume, including blood volume, and assists in maintaining the required acid-base balance.

Some of the fluids recommended by practitioners of sports medicine include plain, cold water, orange juice ($\frac{1}{5}$ strength), cranberry juice ($\frac{1}{6}$ strength), "Gatorade Thirst Quencher," "Exceed Fluid Replacement and Energy Drink," "Quickick," "Sqwincher — The Activity Drink," "10-K," "USA Wet," and "Body Fuel."

DEHYDROCHLORINATION. See **Organic Chemistry**.

DEHYDROGENATION. A reaction resulting in the removal of hydrogen from an organic compound or compounds. This process is brought about in several ways. Simple heating of hydrocarbons to high temperature, as in thermal cracking, causes some dehydrogenation, indicated by the presence of unsaturated compounds and free hydrogen. Catalytic processes often produce commercially practicable yields of selected dehydrogenated products. The enzyme dehydrogenase is a selective catalyst of this character. There is considerable evidence to indicate that many reactions commonly classed as oxidations, e.g., the oxidation of methanol to formaldehyde are actually dehydrogenations, i.e.,



In the chemical process industries, nickel, cobalt, platinum, palladium, and mixtures containing potassium, chromium, copper, aluminum, and other metals are used in very large-scale dehydrogenation processes. For example, acetone (6 billion pounds per year) is made from isopropyl alcohol; styrene (over 2 billion pounds per year) is made from ethylbenzene. The dehydrogenation of *n*-paraffins yields detergent alkylates and *n*-olefins. The catalytic use of rhenium for selective dehydrogenation has increased in recent years. Dehydrogenation is one of the most commonly practiced of the chemical unit processes.

See also **Organic Chemistry**.

DEIONIZATION POTENTIAL. The potential at which conduction in a gas-discharge tube stops, due to the cessation of ionization.

DEIONIZATION TIME. The time required for the grid of a gas-discharge tube to regain control after anode-current interruption. To be exact, the ionization and deionization times of a gas tube should be presented as families of curves relating such factors as condensed-mercury temperature, anode and grid currents, anode and grid voltages, and regulation of the grid current.

DEIONIZING. A method for purifying water that involves two steps. First, soluble salts are converted into acids by passing through a hydrogen exchanger. Second, they are removed by an acid adsorbent or synthetic resin.

See also **Demineralization**.

DEISENHOFER, JOHANN (1943–). Awarded the Nobel Prize for chemistry in 1988, along with Robert Huber and Hartmut Michel, for work that revealed the three-dimensional structure of closely linked proteins that are essential to photosynthesis. Doctorate awarded in 1974 by Max Planck Institute of Biochemistry, Germany.

DE JUSSIEU, ANTOINE-LAURENT (1748–1836). Antoine de Jussieu was a French botanist and founding father of modern plant classification schemes.

Antoine-Laurent de Jussieu was the most famous of the several botanists that carried this illustrious surname, although some botanists today consider his uncle Bernard the greater figure. His ability was recognized early. After a medical training in Paris he became deputy to L. G. Le Monnier, Professor of Botany at the Jardin de Roi. His first publications explored new ways of classifying plants, adopting some of the methods used by Bernard de Jussieu at the Trianon garden, Versailles. Thereafter he concentrated on exploring the natural system of classification, producing a pivotal study *Genera Plantarum* in 1789. In this he made effective use of Michel Adanson's pioneering work and had access to many of the most significant botanical collections in Europe. His categories were highly esteemed by other botanists, and remain a part of modern systems. During the French Revolution Jussieu held a civil position in Paris, but was subsequently appointed Professor of Botany in the reorganized Museé d'Histoire Naturelle. He spent much of his later life expanding and arranging the national herbarium collection. See also **Adanson, Michel (1727–1806)**; and **Taxonomy (The History)**.

DEL. The differential operator used in vector analysis and sometimes also called nabla, since its usual symbol ∇ is thought to resemble an Assyrian harp with the latter name. In Cartesian coordinates it is $(\mathbf{i}\partial/\partial x + \mathbf{j}\partial/\partial y + \mathbf{k}\partial/\partial z)$. When applied to a scalar function it gives the gradient; to vectors, it can give the divergence or the curl.

In the following relations ϕ is a scalar; $\mathbf{U}$, $\mathbf{V}$ are vectors; the asterisk (*) can be either a dot or a cross and, depending on that choice, A, B are either scalars or vectors. $\nabla^*(A+B) = \nabla^*A + \nabla^*B$; $\nabla(\phi A) = \nabla\phi^* A + \phi\nabla^* A$; $\nabla(\mathbf{U}\cdot\mathbf{V}) = (\mathbf{V}\cdot\nabla)\mathbf{U} + (\mathbf{U}\cdot\nabla)\mathbf{V} + \mathbf{V}\times(\nabla\times\mathbf{U}) + \mathbf{U}\times(\nabla\times\mathbf{V})$; $\nabla\cdot(\mathbf{U}\times\mathbf{V}) = \mathbf{V}\cdot\nabla\times\mathbf{U} - \mathbf{U}\cdot\nabla\times\mathbf{V}$; $\nabla\times(\mathbf{U}\times\mathbf{V}) = (\mathbf{V}\cdot\nabla)\mathbf{U} - \mathbf{V}(\nabla\cdot\mathbf{U}) - (\mathbf{U}\cdot\nabla)\nabla + \mathbf{U}(\nabla\cdot\mathbf{V})$. If

$$\mathbf{R} = \mathbf{i}x + \mathbf{j}y + \mathbf{k}z,$$

a position vector, $\nabla\cdot\mathbf{R} = 3$; $\nabla\times\mathbf{R} = 0$; $\mathbf{U}\cdot\nabla\mathbf{R} = \mathbf{U}$.

There are six possible combinations where the operator is applied twice, although two of them equal zero identically. They are: (1) $\nabla^2\phi$, the Laplacian; (2) $\nabla^2\mathbf{V}$; (3) $\nabla(\nabla\cdot\mathbf{V})$; (4) $\nabla\times(\nabla\times\mathbf{V}) = \nabla(\nabla\cdot\mathbf{V}) - \nabla\cdot\nabla\mathbf{V}$; (5) $\nabla\times\nabla\phi$, (6) $\nabla\cdot\nabla\times\mathbf{V} = 0$.

DELAY. Applied to any time-varying physical quantity, usually periodic, its displacement in time relative to a similar reference quantity. for example, the temperature in soil depends on depth and time. If the surface temperature varies sinusoidally, so does the temperature at any depth, but it is out of phase (is delayed) relative to the surface temperature. There is a phase shift or phase delay or phase lag of soil temperature relative to surface temperature. Although these three terms are most often applied to waves, nothing inherent in the concept of a delay restricts it to waves.

See also **Phase**; **Phase Delay**; and **Phase Shift**.

DELAY CIRCUIT. When it is desired to delay the output signal of a device or system for a specified time interval with respect to the input signal, this can be accomplished by use of a delay circuit. See also **Delay Line**.

DELAYED COKING. See **Cracking Process**.

DELAYED NEUTRON. See **Neutron**.

DELAY EQUALIZER. An equalizer used to correct for delay distortion in transmission systems. Usually a corrective network is employed to make the phase delay (or envelope delay) of a system or circuit essentially constant over a desired range of frequency.

DELAY LINE. In communication and control systems, a delay line may be used to hold a signal for a discrete period and then retransmit the

signal with a minimum of distortion. This action can be accomplished in several ways.

In a *magnetostrictive delay line*, electric pulses are converted into acoustical pulses for transmission along a wire and then are reconverted to electric pulses after a delay, depending upon the length of the wire. A simple form of this device consists of two coils, biased with small permanent magnets, which are placed around a strip of magnetostrictive material. A current pulse in the input coil produces a longitudinal stress wave that travels along the wire at about 2×10^5 inches (5.1×10^5 centimeters) per second. When the wave reaches the output coil, it introduces a corresponding pulse. Absorption pads are clamped at the ends of the magnetostrictive strip to eliminate reflected pulses. The device is limited to about 50 microseconds inasmuch as this length of delay occupies a 15-inch (38-centimeter) package, making longer delays rather unwieldy physically. The maximum signal frequency is about 4 MHz and the delay is about 5 microseconds/inch of transmission material.

In a *torsional type magnetostrictive delay line*, the longitudinal stress waves generated in magnetostrictive material are converted to torsional waves in a transmission wire. The torsional pulse induced in the transmission wire travels along in helical fashion at about 1.2×10^5 inches (3×10^5 centimeters) per second. Delays may be as long as 20 milliseconds. Bandpass characteristics are linear over a frequency band equal in width to the center frequency of operation. As an example, a 3-dB bandpass for a line designed to operate at 1 MHz will extend from 0.5 to 1.5 MHz. Lines can be designed to operate at frequencies ranging from 200 kHz to 4 MHz. Principal applications are in electronic memories and recirculating buffers in display systems.

Blocks of glass or quartz also can be used as a medium to transmit acoustical pulses. An electric pulse is converted to an acoustical signal by a transducer on one face of a multifaced block. The signal is totally internally reflected in the block many times before it reaches the receiving transducer on another face. Transducers may be piezoelectric-ceramic or crystalline quartz. Ceramic transducers produce a low loss of about 40 dB at frequencies up to about 10 MHz. Crystalline quartz transducers produce 60- to 80-dB loss, but can be used up to 60 MHz. Longer delays can be generated in glass delay lines and up to 5 milliseconds in fused quartz lines. If ferromagnetic metal is used for the transmission block, the frequency of signals is limited to about 5 or 10 MHz because of absorption of higher frequencies in the metal domains. A glass delay line can be mounted on a circuit board together with integrated circuitry to utilize it as a digital memory. Uses include buffers for computer printers, readouts, and typewriters, in addition to short-time memories for small computers, numerical controls, and electronic calculators.

In connection with pneumatic signals, the delay is about 1 millisecond per foot (0.3 meter) depending upon the propagation velocity of sound waves. Pneumatic delays are used in fluidic circuits to generate time-based functions.

Taped delays can be used in some cases. If a signal is recorded on a moving tape or drum and then read at some distance from the writing head, it will obviously be delayed by the time of transport between reading and writing heads. This approach provides long, easily adjustable delays, but because of the cost and complexity of driving equipment, it is usually available only in special equipment.

Devices used for injecting timed intervals into systems beyond a fraction or few seconds are usually classified as timers rather than delay devices.

DELBRÜCK, MAX LUDWIG HENNING (1906–1981). Delbrück was a German-born physicist, later an American citizen, and founding father of molecular biology.

Max Delbrück was born in Berlin in 1906, the youngest of seven children. He was the great-grandson of the eminent chemist Justus von Liebig, and his father was Professor of History at the University of Berlin. As a boy Delbrück was interested in astronomy, and he went on to study astronomy, physics and mathematics initially at Tübingen, then at Berlin, and finally at the University of Göttingen in Germany. He began a PhD on novae, but found the mathematics of astrophysics particularly difficult. At the time Max Born, Professor of Theoretical Physics at Göttingen, offered him a teaching assistantship. During this time, he also spent 18 months at the H. H. Wills Physics Laboratory at the University of Bristol, England. His PhD on the quantum mechanics of the homopolar bond was awarded in 1930.

In 1931 he was awarded a Rockefeller Physics Scholarship. He spent 6 months studying with Niels Bohr in Copenhagen, and a further 6 months with the quantum physicist Wolfgang Pauli in Zurich. Delbrück was intrigued by Bohr's assertion that biology might be fruitfully studied using the tools and concepts of physics, perhaps yielding laws of atomic physics as yet unknown. This inspired Delbrück to take up the study of biology. In autumn 1932 he accepted a post as assistant to Lise Meitner at the Kaiser Wilhelm Institute for Chemistry in Berlin; this had the advantage of being close to the Kaiser Wilhelm Institute for Biology. There he began a private discussion group consisting of theoretical physicists, biochemists and biologists. This initial collaboration between biologists and physicists culminated in the publication of a joint paper on gene mutation and structure. In this it was suggested that genes must be constituted from molecules with an unusual atomic structure which would allow them to remain stable within the constantly changing cellular environment. The paper attracted little interest at the time, being mathematically complex. Some ten years later Erwin Schrödinger would draw attention to the potential value of physics to the study of biology in his book *What is Life?* In time many physicists would turn their attention to biology.

In 1937 Delbrück was offered a Rockefeller Traveling Fellowship in Biology and he traveled to the California Institute of Technology to study the genetics of *Drosophila* with Thomas Hunt Morgan. The terminology of *Drosophila* genetics proved a barrier for Delbrück, but he happened upon the research of Emory Ellis who was studying viruses that infect bacteria, known as bacteriophages (commonly known as phage). Delbrück saw the phage as a tool for studying the mechanism of the genes and life itself. His first paper on 'The Growth of the Bacteriophage' appeared in the *Journal of General Physiology* in 1938. See also **Morgan, Thomas Hunt (1866–1945)**.

On completion of his fellowship in 1940 he accepted the position of Instructor in Physics at Vanderbilt University, Nashville, Tennessee, where he was able to continue his biological research. In 1941 he married Mary (Manny) Adeline Bruce. He also met Salvador Luria, a worker on phage at the College of Physicians and Surgeons in New York. Together they collaborated on experiments at the Cold Spring Harbor Laboratory for Quantitative Biology in their summer vacations. They demonstrated that bacteria became resistant to phage through mutation. This was the beginning of bacterial genetics as a tool for exploring the molecular basis of life; it was the beginning of molecular biology. In 1943 they were joined by Alfred A. Hershey, a microbiologist, and together they formed the core of the Phage Group, a group of researchers whose aim was to elucidate the mechanism of phage replication. Under the direction of Delbrück they standardized their research, focusing their experiments on a set of seven phages, T1–T7, all of which infected *Escherichia coli* strain B. To facilitate the involvement of physicists in this field of biology they introduced a phage course at Cold Spring Harbor in 1945. This became an annual event which attracted many eminent researchers over the years. In this same year Delbrück became a naturalized American citizen. See also **Hershey, Alfred Day (1908–1997)**.

In 1946 he accepted the Chair of Biology at the California Institute of Technology, declining offers from elsewhere, including the Chair of Biophysics at the University of Manchester, England. Delbrück attracted many students to the study of phage genetics. He succeeded in bringing physics into the biological laboratory, ushering in a new era of molecular biology. In 1949 he delivered an address to the Connecticut Academy of Arts and Sciences entitled 'A Physicist Looks at Biology', and here he thanked Bohr who had inspired his interest in biology. He clearly saw himself as a physicist searching biology for new laws of physics, yet ultimately research on DNA was to reveal that cells were governed by the normal laws of physics. Perhaps because of this failure of phage research to elaborate new laws of physics, in the mid-1950s Delbrück turned his attention to the study of sensory perception and transduction. He studied the phototropic responses of a fungus *Phycomyces*, and he created a research group similar in kind to that which had worked on the phage. This was known as the Phycomyces Group.

For their research on bacteriophages Delbrück, Luria and Hershey were awarded the 1969 Nobel Prize for Medicine or Physiology. Delbrück considered not accepting the award. He believed that the prize and their laureates were being overplayed, to the detriment of medical science. Ultimately he did accept the award, but donated his share of the prize money to Amnesty International. In 1967 he was elected a foreign member of the Royal Society. He retired from research in 1977. Throughout his

career he retained an interest in poetry and classical music. He was a keen family man and had two sons and two daughters. After a long struggle with cancer he died in 1981. In this year, an extension to the Davenport Laboratory at Cold Spring Harbor was named the Max Delbrück Laboratory in his honor.

DELIQUESCENCE. When a substance absorbs moisture upon exposure to the atmosphere, the substance is said to be *deliquescent*. At ordinary temperatures the vapor pressure of water varies as shown in Table 1. If the solution of a substance in water has a lower water vapor pressure than that of the atmosphere at the given temperature, water vapor condenses in the solution from the atmosphere until the water vapor pressure of the solution equals the water vapor pressure of the surrounding atmosphere.

TABLE 1. VARIATION OF WATER VAPOR PRESSURE WITH TEMPERATURE

Temperature °C	Water Vapor Pressure in mm of Mercury	
	At Saturation	At 50% Humidity
0	4.6	2.3
10	9.2	4.6
20	17.5	8.8
30	31.8	15.9
40	55.3	27.7

Substances that are ordinarily deliquescent are sulfuric acid (concentrated), glycerol, calcium chloride crystals, sodium hydroxide (solid), and 100% ethyl alcohol. In an enclosed space, these substances deplete the water vapor present to a definite degree. Other substances are used to accomplish this end by chemical reaction, e.g., phosphorus pentoxide (forming phosphoric acid), and boron trioxide (forming boric acid). Water is absorbed from nonmiscible liquids by addition of such substances as anhydrous sodium sulfate, potassium carbonate, anhydrous calcium chloride, and solid sodium hydroxide. The converse phenomenon is known as *efflorescence*.

DELTA. The terminal deposit of river borne sediment in a lake or bay. So called because of its triangular or delta-like ground plan. The cross section or structure of a typical delta is shown in Fig. 1. Except in the case of small deltas only the top-set beds can be observed. In the case of Paleozoic, Mesozoic, and Cenozoic deltas, it is extremely difficult to distinguish between the top-set, fore-set, and bottom-set beds, and the ultimate determination that a sedimentary formation is of delta origin depends largely on tracing the original source and areal distribution of the sediments, and the presence or absence of marine and terrestrial fossils.

See also **Estuary**.

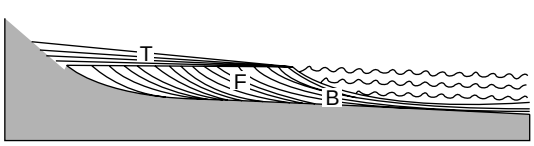

Fig. 1. Ideal structure of a delta: (*T*) top-set beds; (*B*) bottom-set beds; (*F*) forest beds.

DELTA CONNECTION. The Delta connection is one of the two most frequently used ways of connecting a three-phase alternating-current circuit. The other is the Y connection. A three-phase machine has three coils. These coils have six ends, which must, in some way, be connected to the three wires of a three-phase circuit. The Delta connection, as illustrated in Fig. 1, has the coils connected at three points corresponding to the three-phase circuit. When this is compared with the Y connection, it will become apparent that the line voltage in the Delta connection equals the coil voltage, and that the line current in the Y connection equals coil current. For a balanced Delta load, the current in each line is $\sqrt{3}$ times the phase (or coil) current. It is also the π configuration of a two-part network.

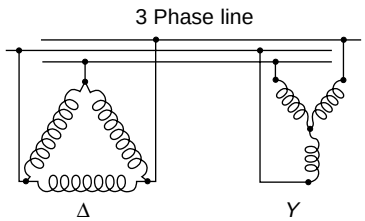

Fig. 1. Comparison of delta and Y connections.

DELTA FUNCTION. Commonly written as $\delta(x)$, it lies outside the usual scope of function theory. It can be defined by the relation

$$\int_a^b \phi(x)\delta(x - x_0)dx = \phi(x_0)$$

where ϕ(x) is continuous and $a \leq x_0 \leq b$. It can thus be thought of as a function which is zero for every value of x except the origin, where it is infinite in such a way that

$$\int_a^b \delta(x)dx = 1, \quad a < 0 < b$$

The delta function has played an important role in mathematical physics and applied mathematics since it can be used to represent idealizations such as point charge, or point load, which lead to Green's functions of the differential equations representing various field theories. See also **Dirac Delta Function**.

DEMAGNETIZING FIELD. A body of magnetic material subject to an applied magnetizing force H_a is acted upon by a net magnetizing force

$$H = H_a - \Delta H$$

where the demagnetizing field ΔH is interpreted as being due to the poles induced on the surface of the body. In the case of a permanent magnet with $H_a = 0$, the demagnetizing field is readily seen to be the field of the magnet itself, which always has such a direction as to oppose the magnetization. The existence of a demagnetizing field is a necessary consequence of the fact that energy is stored in the field external to the magnetized body, and that the sum of this energy and the internal energy must be minimized at equilibrium.

DEMAL SOLUTION. A solution which contains one gram-equivalent of solute per cubic decimeter of solution. It is slightly weaker than a normal solution, in the ratio of the magnitude of the liter to the cubic decimeter.

DEMINERALIZATION. Removal from water of mineral contaminants, usually present in ionized form. The methods used include ion-exchange techniques, flash distillation, or electrodialysis. Acid mine wastes may be purified in this way, thus alleviating the pollution problem.

See also **Deionizing**; and **Ion-Exchange Resins**.

DEMODULATOR. The process by which information is derived from a modulated waveform about the signal imparted to the waveform in modulation is termed *demodulation* — and the devices used to accomplish this function are called *demodulators*.

The *rectifier demodulator*, a device consisting of a diode or diodes through which the amplitude-modulated carrier is passed. The resulting

rectified output has an average value proportional to the original modulation. With conditions approximating a perfect rectifier, the linearity of the device is quite good below 10% modulation.

The *envelope demodulator*, a rectifier demodulator whose output is shunted by a capacitance, thus causing the output to be proportional to the peaks of the rectified amplitude-modulated carrier. If low distortion is desired, this process may be used only where the ratio of carrier to the highest modulation frequency is quite large.

The *frequency demodulator*, a device that will produce an output proportional to the variation of the instantaneous frequency of the input voltage. Ideally it will be insensitive to variations in the amplitude of the input wave.

The *product demodulator*, a device whose output is the product of its two inputs, these being the amplitude-modulated carrier and a locally generated voltage of carrier frequency. This is basically the same device as a product modulator, and with proper filtering, can produce an output proportional to the original modulation.

The *square law demodulator*, a device whose output voltage is proportional to the square of its input voltage. An amplitude-modulated carrier passing through such a device produces an output containing the original modulation signal as well as distortion products. The distortion products increase rapidly as the percent modulation increases.

DEMOSPONGIAE. A class of sponges (*Porifera*) of complex structure, including the sponges of commerce and the freshwater sponges.

The members of this class have siliceous spicules which are never 6-rayed, a spongin skeleton, or a combination of spongin and siliceous matter. Some species have no skeleton. The body plan is of the rhagon type.

These orders are recognized:

Order *Myxospongida*. Simple sponges without skeletal structures.

Order *Monaxonida*. Monaxonid spicules only present.

Order *Tetraxonida*. Skeleton siliceous, sometimes with spongin. Freshwater sponges are included in this order with many marine forms.

Order *Keratosa*. Skeleton of spongin fibers. Spicules absent. Commercial sponges belong here.

DEMULSIFICATION. The process of destroying or ”breaking”and unwanted emulsion, especially water-in-oil types occurring in crude petroleum. Both chemical and physical means are used. Chemical means include addition of polyvalent ions to neutralize electrical charges or of a strong acid; physical means include heating, centrifuging, or use of high-potential alternating current.

See also **Emulsions**.

DENDRITE. A tree-like crystal formed during solidification of metals or alloys. Dendrites generally grow inward from the surface of the mold, extending branches from a central trunk in a manner resembling a fir tree. In alloys, the central portions of a dendritic crystal are richer in higher melting point constituents, while the outer portions consist of lower melting point material, which is last to solidify. This form of segregation can usually be eliminated by diffusion during subsequent mechanical working and heat treatment.

The reasons for the branched growth of a crystal into a liquid that of the temperature of which falls ahead of, the solid, are easily understood. Whenever a small section of the interface is ahead of the surrounding surface, it will be in contact with liquid metal at a lower temperature. Its growth velocity will be increased relative to the surrounding surface, which is in contact with liquid at a higher temperature, and the formation of a spike is only to be expected. Associated with the formation of each spike is the release of a quantity of heat (latent heat of fusion). This heat raises the temperature of the liquid adjacent to any given spike and retards the formation of other similar projections on the general interface in its immediate vicinity. The net result is that a number of spikes of almost equal spacing are formed which grow parallel to each other in the fashion shown in Fig. 1. The *dendritic growth direction* depends upon the crystal structure of the metal.

The branches, or spikes, in Fig. 1 are primary in nature. Once they have formed growth at the general interface will be slow because here the supercooling is small and the latent heat of fusion associated with the formation of the spikes tends to further decrease its magnitude. At section *bb* in Fig. 2 on the other hand, the average temperature of the liquid is, by definition, lower than at *aa*. However, even on this section at points in the liquid close to the spikes the temperature will be higher than midway between the spikes ($T_A > T_B$) because of the latent heat released at the spikes. There is, therefore, a decreasing temperature gradient not only in front of the primary spikes, but also in directions perpendicular to the primary branches. This temperature gradient is responsible for the formation of secondary branches, which form at more or less regular intervals along the primary branches, as shown in Fig. 3.

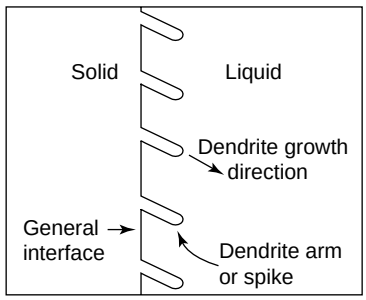

Fig. 1. Schematic representation of the first stage of dendritic growth. A temperature inversion is assumed to exist at the interface i.e., the temperature in the liquid drops in advance of the interface.

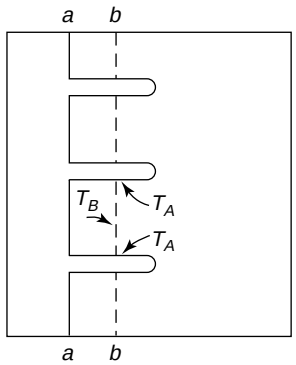

Fig. 2. Secondary dendrite arms form because there is a falling temperature gradient starting at a point close to a primary arm and moving to a point midway between the primary arms.

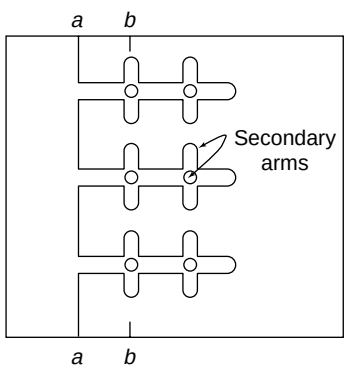

Fig. 3. In a cubic crystal, primary and secondary arms are normal to each other.

DENDROCHRONOLOGY. The analysis of the annual growth rings of trees, leading to the calculation of significant indices of climate and general chronology of the past. The width of a tree ring was determined

by the temperature and/or the moisture that prevailed during the year of its formation. Since stress from temperature and/or moisture variations reduces the width of the seasonal growth of a tree ring, dendrochronology has important application in the study of long-term climatic variations. This technique was invented and developed during the 20th century originally by A. E. Douglass, the founder of the Laboratory of Tree-Ring Research at the University of Arizona http://www.ltrr.arizona.edu/. The technique can date wood to exact calendar years.

Overview

Many trees in temperate zones grow one growth ring each year, the newest ring being under the bark. For the entire period of a tree's life, a year-by-year record or ring pattern is formed that reflects the climatic conditions in which the tree grew. Adequate moisture and a long growing season result in a wide ring. A drought year may result in a very narrow one. Trees from the same region will tend to develop the same patterns of ring widths for a given period. These patterns can be compared and matched ring for ring with trees growing in the same geographical zone and under similar climatic conditions. Following these tree-ring patterns from living trees back through time, chronologies can be built up. Thus wood from ancient structures can be matched to known chronologies (a technique called *cross-dating*) and the age of the wood determined precisely. Cross-dating was originally done by visual inspection. Nowadays, computers are used to do the statistical matching.

To eliminate individual variations in tree ring growth, dendrochronologists take the smoothed average of the tree ring widths of multiple tree samples to build up a ring history. This process is termed replication. A tree ring history whose beginning and end dates are not known is called a *floating chronology*. It can be anchored by cross-matching either the beginning or the end section against the end sections of another chronology (tree ring history) whose dates are known. Fully anchored chronologies which extend back more than 10,000 years exist for river oak trees from South Germany (from the Main and Rhine rivers). A fully anchored chronology which extends back 8500 years exists for the bristlecone pine in the southwest US (White Mountains of California).

DENGUE FEVER AND DENGUE HEMORRHAGIC FEVER. Dengue and dengue hemorrhagic fever (DHF) are caused by one of four closely related, but antigenically distinct, virus serotypes (DEN-1, DEN-2, DEN-3, and DEN-4), of the genus Flavivirus. Infection with one of these serotypes does not provide cross-protective immunity, so persons living in a dengue-endemic area can have four dengue infections during their lifetimes. Dengue is primarily a disease of the tropics, and the viruses that cause it are maintained in a cycle that involves humans and *Aedes aegypti*, a domestic, day-biting mosquito that prefers to feed on humans. Infection with dengue viruses produces a spectrum of clinical illness ranging from a nonspecific viral syndrome to severe and fatal hemorrhagic disease. Important risk factors for DHF include the strain and serotype of the infecting virus, as well as the age, immune status, and genetic predisposition of the patient.

History of Dengue

The first reported epidemics of dengue fever occurred in 1779–1780 in Asia, Africa, and North America; the near simultaneous occurrence of outbreaks on three continents indicates that these viruses and their mosquito vector have had a worldwide distribution in the tropics for more than 200 years. During most of this time, dengue fever was considered a benign, nonfatal disease of visitors to the tropics. Generally, there were long intervals (10–40 years) between major epidemics, mainly because the viruses and their mosquito vector could only be transported between population centers by sailing vessels.

A global pandemic of dengue began in Southeast Asia after World War II and has intensified during the last 15 years. Epidemics caused by multiple serotypes (hyperendemicity) are more frequent, the geographic distribution of dengue viruses and their mosquito vectors has expanded, and DHF has emerged in the Pacific region and the Americas. In Southeast Asia, epidemic DHF first appeared in the 1950s, but by 1975 it had become a leading cause of hospitalization and death among children in many countries in that region.

Current Trends

In the 1980s, DHF began a second expansion into Asia when Sri Lanka, India, and the Maldive Islands had their first major DHF epidemics; Pakistan first reported an epidemic of dengue fever in 1994. The recent epidemics in Sri Lanka and India were associated with multiple dengue virus serotypes, but DEN-3 was predominant and was genetically distinct from DEN-3 viruses previously isolated from infected persons in those countries. After an absence of 35 years, epidemic dengue fever occurred in both Taiwan and the People's Republic of China in the 1980s. The People's Republic of China had a series of epidemics caused by all four serotypes, and its first major epidemic of DHF, caused by DEN-2, was reported on Hainan Island in 1985. Singapore also had a resurgence of dengue/DHF from 1990 to 1994 after a successful control program had prevented significant transmission for over 20 years. In other countries of Asia where DHF is endemic, the epidemics have become progressively larger in the last 15 years.

In the Pacific, dengue viruses were reintroduced in the early 1970s after an absence of more than 25 years. Epidemic activity caused by all four serotypes has intensified in recent years with major epidemics of DHF on several islands.

Despite poor surveillance for dengue in Africa, epidemic dengue fever caused by all four serotypes has increased dramatically since 1980. Most activity has occurred in East Africa, and major epidemics were reported for the first time in the Seychelles (1977), Kenya (1982, DEN-2), Mozambique (1985, DEN-3), Djibouti (1991–92, DEN-2), Somalia (1982, 1993, DEN-2), and Saudi Arabia (1994, DEN-2). Epidemic DHF has been reported in neither Africa nor the Middle East, but sporadic cases clinically compatible with DHF have been reported from Mozambique, Djibouti, and Saudi Arabia.

The emergence of dengue/DHF as a major public health problem has been most dramatic in the American region. In an effort to prevent urban yellow fever, which is also transmitted by *Ae. aegypti*, the Pan American Health Organization organized a campaign that eradicated *Ae. aegypti* from most Central and South American countries in the 1950s and 1960s. As a result, epidemic dengue occurred only sporadically in some Caribbean islands during this period. The *Ae. aegypti* eradication program, which was officially discontinued in the United States in 1970, gradually eroded elsewhere, and this species began to reinfest countries from which it had been eradicated. In 1997, the geographic distribution of *Ae. aegypti* is wider than its distribution before the eradication program. See Fig. 1.

In 1970, only DEN-2 virus was present in the Americas, although DEN-3 may have had a focal distribution in Colombia and Puerto Rico. In 1977, DEN-1 was introduced and caused major epidemics throughout the region over a 16-year period. DEN-4 was introduced in 1981 and caused similar widespread epidemics. Also in 1981, a new strain of DEN-2 from Southeast Asia caused the first major DHF epidemic in the Americas (Cuba). This strain has spread rapidly throughout the region and has caused outbreaks of DHF in Venezuela, Colombia, Brazil, French Guiana, Suriname, and Puerto Rico. By 1997, 18 countries in the American region had reported confirmed DHF cases, (Fig. 2.), and DHF is now endemic in many of these countries.

DEN-3 virus recently reappeared in the Americas after an absence of 16 years. This serotype was first detected in association with a 1994 dengue/DHF epidemic in Nicaragua. Almost simultaneously, DEN-3 was confirmed in Panama and, in early 1995, in Costa Rica. In Nicaragua, considerable numbers of DHF cases were associated with the epidemic, which was apparently caused by DEN-3. In Panama and Costa Rica, the cases were classic dengue fever.

Viral envelope gene sequence data from the DEN-3 strains isolated from Panama and Nicaragua have shown that this new American DEN-3 virus strain was likely a recent introduction from Asia since it is genetically distinct from the DEN-3 strain found previously in the Americas, but is identical to the DEN-3 virus serotype that caused major DHF epidemics in Sri Lanka and India in the 1980s. As suggested by the finding of a new DEN-3 strain, and the susceptibility of the population in the American tropics to it DEN-3 spread rapidly throughout the region caused major epidemics of dengue/DHF in Central America in 1995.

In 1997, dengue is the most important mosquito-borne viral disease affecting humans; its global distribution is comparable to that of malaria, and an estimated 2.5 billion people live in areas at risk for epidemic transmission. See Fig. 3. Each year, tens of millions of cases of dengue fever occur and, depending on the year, up to hundreds of thousands of cases of DHF. The case-fatality rate of DHF in most countries is about 5%; most fatal cases are among children and young adults.

There is a small, but significant, risk for dengue outbreaks in the continental United States. Two competent mosquito vectors, *Ae. aegypti*

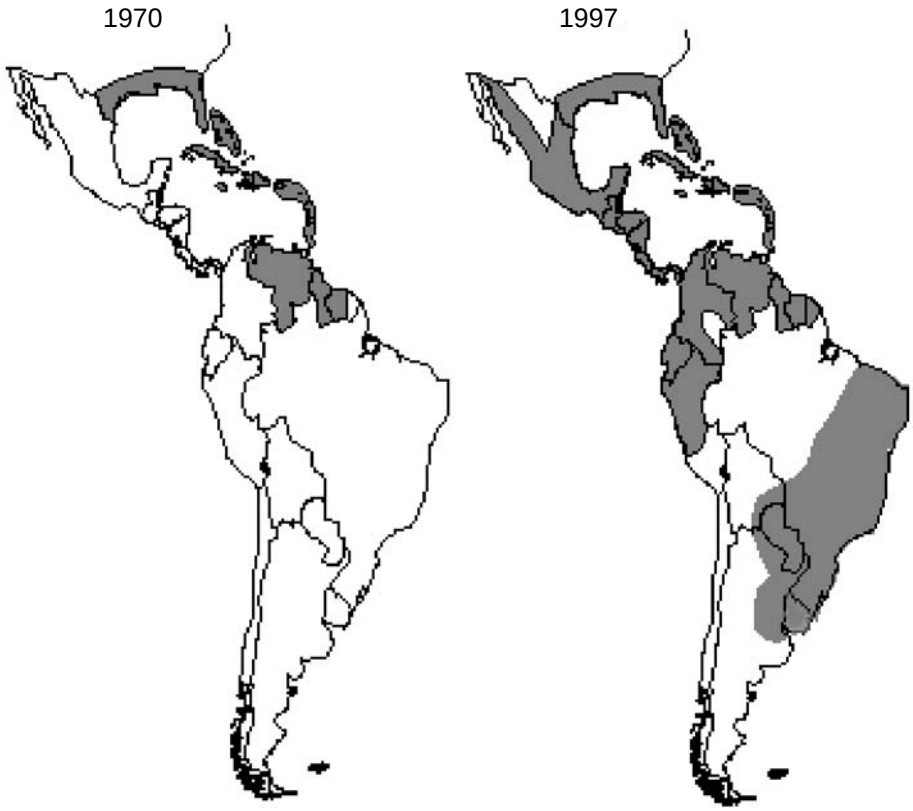

Fig. 1. Distribution of *Aedes aegypti* (shaded areas) in the Americas in 1970, at the end of the mosquito eradication program, and in 1997.

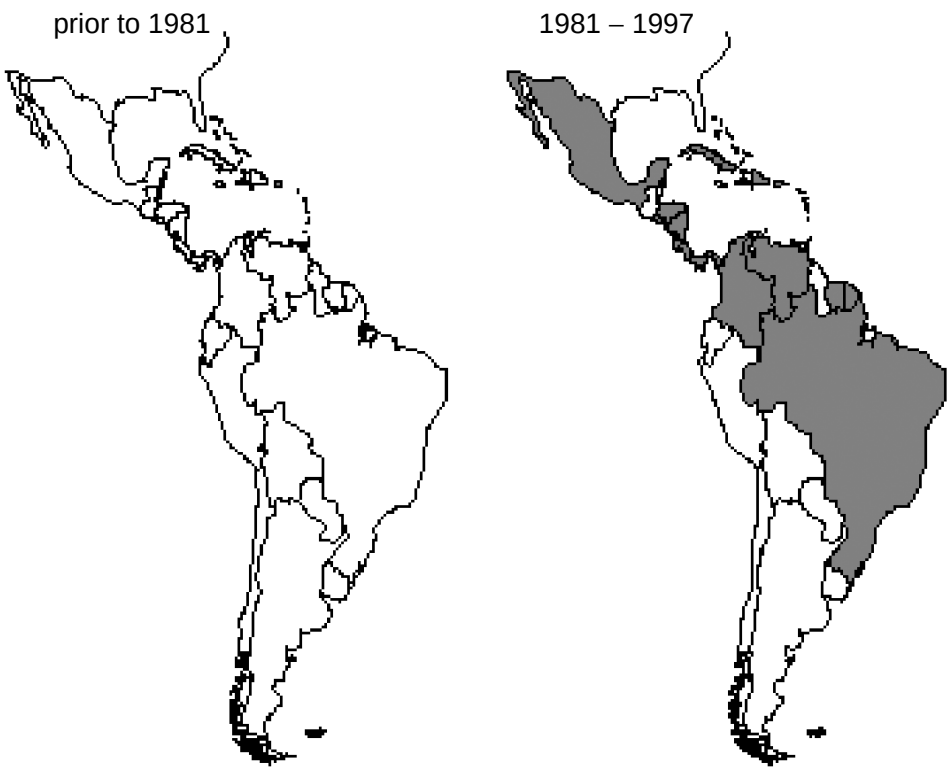

Fig. 2. American countries with laboratory-confirmed dengue hemorrhagic fever (shaded areas), prior to 1981 and from 1981 to 1997.

and *Aedes albopictus*, are present and, under certain circumstances, each could transmit dengue viruses. This type of transmission has been detected three in the last 16 years in south Texas (1980, 1986, and 1995) and has been associated with dengue epidemics in northern Mexico. Moreover, numerous viruses are introduced annually by travelers returning from tropical areas where dengue viruses are endemic. From 1977 to 1994, a total of 2,248 suspected cases of imported dengue were reported in the United States. Although some specimens collected were not adequate for laboratory diagnosis, 481(21%) cases were confirmed as dengue. Many more cases probably go unreported each year because surveillance in

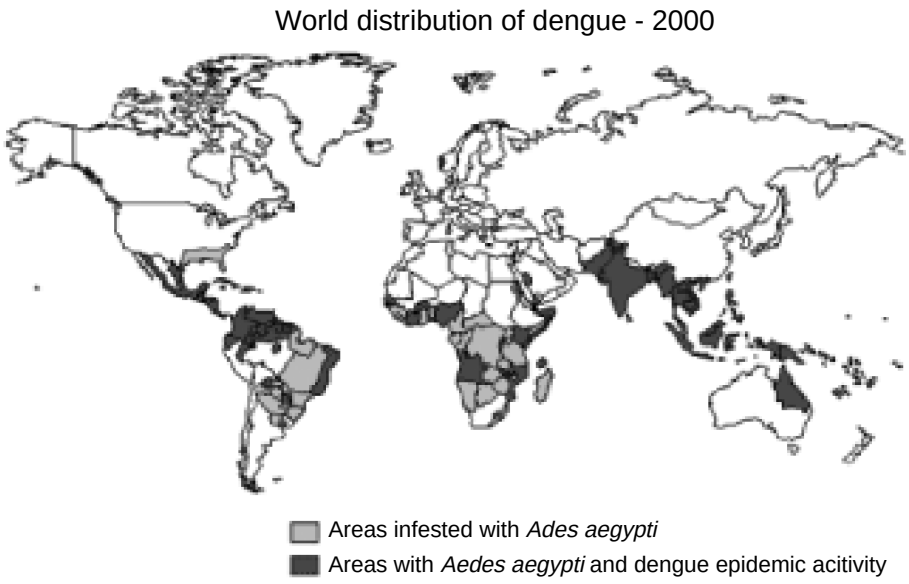

Fig. 3. World distribution of dengue viruses and their mosquito vector, *Aedes aegypti*, in 1997.

the United States is passive and relies on physicians to recognize the disease, inquire about the patient's travel history, obtain proper diagnostic samples, and report the case. These data suggest that southern Texas and the southeastern United States, where *Ae. aegypti* is found, are at risk for dengue transmission and sporadic outbreaks.

The reasons for this dramatic global emergence of dengue/DHF as a major public health problem are complex and not well understood. However, several important factors can be identified. First, effective mosquito control is virtually nonexistent in most dengue-endemic countries. Considerable emphasis for the past 20 years has been placed on ultra-low-volume insecticide space sprays for adult mosquito control, a relatively ineffective approach for controlling *Ae. aegypti*. Second, major global demographic changes have occurred, the most important of which have been uncontrolled urbanization and concurrent population growth. These demographic changes have resulted in substandard housing and inadequate water, sewer, and waste management systems, all of which increase *Ae. aegypti* population densities and facilitate transmission of *Ae. aegypti* -borne disease. Third, increased travel by airplane provides the ideal mechanism for transporting dengue viruses between population centers of the tropics, resulting in a constant exchange of dengue viruses and other pathogens. Lastly, in most countries the public health infrastructure has deteriorated. Limited financial and human resources and competing priorities have resulted in a "crisis mentality" with emphasis on implementing so-called emergency control methods in response to epidemics rather than on developing programs to prevent epidemic transmission. This approach has been particularly detrimental to dengue control because, in most countries, surveillance is (just as in the U.S.) very inadequate; the system to detect increased transmission normally relies on reports by local physicians who often do not consider dengue in their differential diagnoses. As a result, an epidemic has often reached or passed transmission before it is detected.

Future Outlook

No dengue vaccine is available. Recently, however, attenuated candidate vaccine viruses have been developed in Thailand. These vaccines are safe and immunogenic when given in various formulations, including a quadrivalent vaccine for all four dengue virus serotypes. Efficacy trials in human volunteers have yet to be initiated. Research is also being conducted to develop second-generation recombinant vaccine viruses; the Thailand attenuated viruses are used as a template. Therefore, an effective dengue vaccine for public use will not be available for 5 to 10 years.

Prospects for reversing the recent trend of increased epidemic activity and geographic expansion of dengue are not promising. New dengue virus strains and serotypes will likely continue to be introduced into many areas where the population densities of *Ae. aegypti* are at high levels. With no new mosquito control technology available, in recent years public health authorities have emphasized disease prevention and mosquito control through community efforts to reduce larval breeding sources. Although this approach will probably be effective in the long run, it is unlikely to impact disease transmission in the near future. Improved, proactive, laboratory-based surveillance systems that can provide early warning of an impending dengue epidemic must be developed. At the very least, surveillance results can alert the public to take action and physicians to diagnose and properly treat dengue/DHF cases.

Division of Vector-Borne Infectious Diseases, Fort Collins, Co., National Center for Infectious Diseases, and Centers for Disease Control and Prevention (CDC), Atlanta, GA.

DENITRIFICATION. 1. The conversion of nitrite or nitrate to gaseous end products NO, N_2O, and N_2 by denitrifying bacteria. Molecular nitrogen, N_2, is the most abundant end product. The oxidized forms of N (nitrate, nitrite, nitric acid, nitric oxide, and nitrous oxide) serve as alternative electron acceptors in the absence of sufficient oxygen; thus, denitrification is primarily an anaerobic process.

2. The removal of active nitrogen from the atmosphere through uptake into particles. The term is particularly used in context with the irreversible uptake of nitric acid into ice clouds (polar stratospheric clouds) in the antarctic stratospheric vortex. This reduction in the level of active nitrogen allows ozone depletion by chlorine oxides to occur unchecked.

AMS

DENSE. A set T of a space S is dense in S if every point of S is a point or limit point of T, or in other words, if the closure of T is S.

DENSITY. The density of a substance is its mass per unit volume, usually expressed in grams per cubic centimeter. The specific gravity of the substance is the ratio of its density to that of water, usually at 4 °C, or 20 °C, or 60 °F, in the same units, and is therefore an abstract number independent of units. The density of a body is the ratio of its mass to its volume.

To determine the density of a given substance, it is necessary only to ascertain the volume of a specimen whose mass is known by weighing. This may be obtained from measurements on the dimensions of the specimen, or, in the case of a liquid, by the use of a pycnometer or specific gravity bottle. For solids a more precise method is to measure the buoyant force, upon the specimen, of a liquid of known density in which it is immersed, or by enclosing it in a gravity bottle and determining the volume by displacement. The Mohr-Westphal balance is especially designed to give densities of liquids by the buoyant force on a solid sinker of known volume. The hydrometer may also be used for quick determinations of liquid densities. The density of a gas is best obtained by weighing a specimen of it in a large, light bulb of known capacity, concurrently observing the temperature and pressure to which the gas is subjected, much as the pycnometer is used for liquids.

See Table 1 for a brief list of densities, all in grams per cubic centimeter. For gases the densities are at standard temperature and pressure. The term density is also applied in length-force-time systems of units, to the weight per unit volume. Other meanings of the term density are the blackness of the image on a photographic plate or film and the ratio of the number of particles or total amount of such a quantity as energy or momentum, carried by or contained in a volume, to that volume. Thus one speaks of energy density, electron density, charge density, etc.

TABLE 1. BRIEF LIST OF DENSITIES

Substance	Density	Substance	Density
Air	0.001293	Gold	19.3
Alcohol	0.794	Hydrogen	0.0000899
Aluminum	2.70	Iron	7.86
Carbon dioxide	0.001977	Lead	11.3
Chlorine	0.003214	Mercury	13.55
Copper	8.90	Nitrogen	0.001251
Cork	0.24	Oxygen	0.001429
Gasoline	0.67	Platinum	21.45
Glass	2.4–2.8	Silver	10.5
Glycerine	1.27	Water (4 °C)	0.999973

This last usage has given rise to a number of specific applications of the term density. Thus, the *luminous density* is the luminous energy found in a unit volume of space. The *specular density* is the logarithm of the reciprocal of the specular transmittance, and so on.

DENSITY (Chemical Elements). See **Chemical Elements**.

DENTAL CARIES. See **Caries, Cariology, and Dentistry**; and **Fluorine**.

DENTIFRICES. Dentifrices are compositions designed to be used with a toothbrush. The two essential functions of dentifrices are to remove dental stains and to introduce a fresh, cool, pleasant, and clean feeling into the oral cavity. In the 1960s, a third function was introduced, delivery to the dentition of the therapeutic chemical agent fluoride. Subsequently, agents offering specific therapeutic and nontherapeutic benefits were added to dentifrices. The three forms of marketed dentifrices are pastes (toothpastes), liquid concentrates, and powders. Pastes account for an overwhelming portion of the dentifrice market. Liquid concentrates and powders account for only a minor portion because they have disadvantageous dispensing characteristics and they do not provide a means to accurately and consistently dispense a dose of active agent.

Dentifrices and dental rinses have many common purposes and ingredients, thus dental rinses are discussed briefly herein.

Dental Plaque

Dental plaque, a mass of bacteria that develops around teeth in all people, is the primary cause of dental caries and diseases of the periodontium. Following dental prophylaxis, a tooth becomes covered with a thin film, or pellicle, selectively deposited from the saliva. Bacteria in the oral cavity attach to the pellicle. The early colonizers are predominantly gram-positive bacteria. The bacterial population increases and undergoes a predictable pattern of change as it approaches maturity. Supragingival and subgingival plaque masses are distinguishable. Supragingival plaque matures in about 10 to 12 days, at which time calcification of the mass may be observed (calculus, tartar). The maturation process may be altered by intervening events, such as toothbrushing. The microbial population may generate acids, which cause dental caries, and toxins, which cause irritation of the gingiva, depending on environmental and other factors. See also **Caries, Cariology, and Dentistry**.

Mechanical removal of plaque is the most effective measure against plaque-caused diseases, dental caries, and periodontal diseases. Even before the advent of fluoride treatments, it was assumed that a clean tooth does not decay. A toothbrush is effective in removing dental plaque and, for those individuals who optimize its use, it usually can adequately control plaque. Despite the proven efficacy of mechanical plaque removal, the amount of patient involvement is such that only about 30% of the population in developed countries and considerably less in undeveloped countries can be expected to adequately remove plaque. Hence, supplementary measures such as dentifrices and dental rinses are necessary.

Studies have shown that compliance with toothbrushing would be severely impaired if the brushing regimen did not include dentifrices. Thus, the role of dentifrices in plaque control is to enhance the toothbrushing experience and thereby enhance the results. Dentifrices have little direct effect on plaque removal or accumulation unless they contain agents that have specific antiplaque properties.

Toothpastes

The earliest known reference to a toothpaste is in a manuscript from Egypt in the 4th century A.D., which prescribes a mixture of powdered salt, pepper, mint leaves, and iris flowers. The Romans used toothpaste formulations based on human urine. Since urine contains ammonia, it was probably effective in whitening teeth. An 18th century American toothpaste recipe containing burnt bread has been found. Another formula around this time called for dragon's blood, cinnamon, and burnt alum. See also http://www.toothpasteworld.com/history.htm.

However, toothpastes or powders did not come into general use until the 19th century. In the early 1800s, the toothbrush was usually used only with water, but tooth powders soon gained popularity. Most were home made, with chalk, pulverized brick, and salt being common ingredients. An 1866 Home Encyclopedia recommended pulverized charcoal, and cautioned that many patented tooth powders then commercially marketed did more harm than good.

By 1900, a paste made of hydrogen peroxide and baking soda was recommended. Pre-mixed toothpastes were first marketed in the 19th century, but did not surpass the popularity of tooth-powder until World War I. In New York City in 1896, Colgate & Company manufactured toothpaste in the first collapsible tube, similar to that recently introduced for artists' paints.

Fluoride started to be added to toothpastes in 1914, but while the early use of fluoride was criticized by the American Dental Association (ADA) in 1937, fluoride toothpastes developed in the 1950s got the ADA's seal of approval. Countries limit and suggest different amounts acceptable for health. Much of Africa has a slightly higher percent than the U.S.

Toothpastes are packaged in flexible tubes, other flexible containers, and mechanically operated pump dispensers. They are usually extruded as cylindrical ribbons of a cohesive, smooth paste. New or modified dispensing devices are continually introduced to increase consumer interest.

The addition of therapeutic or cosmetic agents to dentifrices has paralleled advances in knowledge about factors affecting the human dentition. Agents added to dentifrices can act directly on the host tooth structure or on specific oral accumulations, for example, the principal action of fluoride is on the tooth enamel. The primary action of an abrasive, however, is on an accumulated stained pellicle. Oral accumulations of interest to preventive dentistry are dental pellicles, dental plaque, dental calculus (tartar), microbial populations responsible for oral malodor, and oral debris (food residues, leukocytes, etc.). Plaque is most important because of its potential to do harm.

The key functions of dentifrices, to remove dental stains and to freshen the oral cavity, are accomplished by abrasive cleaning and the masking or elimination of unpleasant oral odors. Materials designed to deliver antitartar, antiplaque, or anticaries benefits must be compatible with the ability of the dentifrice to fulfill those two functions.

Toothpaste contains an abrasive, flavor, a humectant system, a surfactant, a binding and thickening agent, color, and one or more therapeutic or cosmetic agents.

Abrasive

Dentifrices have the unique ability to remove extrinsic tooth stains, which are caused by agents such as berries, tea, smoking, antibiotics, and certain bacteria as they attach to the dental pellicle. These stains can be removed only by abrasive cleaning; a toothbrush alone is not adequately effective. It has been shown that only 4% of a test population were able to maintain their teeth in an acceptably stain-free state without an abrasive and that 18% of the population were "heavy" stainers. However, colored materials found in dental plaque are removable without abrasives.

Many abrasive materials have been incorporated into dentifrices to remove stained pellicles. These are generally particles of insoluble inorganic materials and are characterized for dentifrice application by five interdependent parameters: particle size, shape, hardness, toughness, and chemical inertness. Particle size is limited by safety and comfort. The larger the particle, the more it abrades and the more readily it can be detected in the mouth as a gritty foreign material. Most abrasives for dentifrices have an average particle diameter of about 3 to 12 μm. Particles of 30 μm or larger are detected as gritty. The particle shape should be almost spherical, with no protuberances. Sharp points scratch the surface of the tooth. Hardness is governed by the hardness of dentin; on Mohs' scale the hardness of dentin is 2–2.5 and the hardness of dental enamel is 4–5. (Hardness values of talc [CAS: 14807-96-6] and quartz [CAS: 14808-60-7] are 1 and 7, respectively, on Mohs' scale). A hardness of about 2.5 for the abrasive material is adequate to assure that the stained pellicle is safely removed. Toughness is an expression of the tendency of the particle to break down under the force of toothbrushing. Some materials appear to be too hard for use as an abrasive. These can be used, however, if they break down during toothbrushing to particles too small to harm dentin or enamel.

An abrasive is usually chemically inert, neither interacting with other dentifrice ingredients nor dissolving in the paste or the mouth. Substances used as dentifrice abrasives include amorphous hydrated silica, dicalcium phosphate dihydrate [CAS: 7789-77-7], anhydrous dicalcium phosphate [CAS: 7757-93-9], insoluble sodium metaphosphate [CAS: 10361-03-2], calcium pyrophosphate [CAS: 35405-51-7], -alumina trihydrate, and calcium carbonate [CAS: 471-34-1]. These materials are usually synthesized to specifications for purity, particle size, and other characteristics; naturally occurring minerals are used infrequently. Sodium bicarbonate [CAS: 144-55-8] and sodium chloride [CAS: 7647-14-5] have also been employed as dentifrice abrasives.

Methods have been developed to quantify the abrasiveness of dental abrasives. Numerical values are assigned based on the amount of dentin removed by toothbrushing using a standardized slurry of abrasive or total dentifrice under standardized conditions, and comparison with a reference abrasive. One popular measure is the radioactive dentin abrasion value (RDA). This value is obtained by subjecting an excised bovine tooth to a neutron flux, mounting segments of the irradiated tooth dentin in a special brushing machine, and brushing under standardized conditions. The amount of ^{32}P removed is compared with the amount of ^{32}P removed using a reference calcium pyrophosphate abrasive set at 500. The RDA of the total finished product is also measured, because the apparent abrasiveness of an abrasive can be modified by the presence of other ingredients of the formulation. Safe and effective RDA values are in the range of about 50 to 250. See also **Abrasives**.

Flavor

Dentifrices are used to refresh the oral cavity. Flavor oils and other flavoring materials are key to that function. See also **Flavors and Essences**. Generally recognized as safe (GRAS) flavors or flavors from approved lists are used. The most popular flavors are peppermint [CAS: 8006-90-4], spearmint [CAS: 8008-79-5], cinnamon [CAS: 8006-79-9], and mixtures of these. Menthol is a principal constituent of the mint flavors and a source of refreshment and coolness. The concentration of the flavor in the dentifrice and the nature of substances added to bring out specific flavor notes and thereby make the flavor unique are significant concerns. The flavor must not be excessive; it must not burn too strongly. Also, the flavor must not be a sensitizer. Synthetic sweeteners are usually added, although regulatory concerns limit their selection; for example, cyclamate [CAS: 100-88-9] is not used in the United States.

Humectant System

The humectant system comprises one or more liquids in which the other toothpaste ingredients are dispersed to provide a stable paste. The liquids are usually glycerol and 70% aqueous sorbitol. Propylene glycol [CAS: 57-55-6] and polyethylene glycols are used occasionally. The liquids are used alone or in combination. Their water activity is such that they do not support bacteriological growth. The humectant system does not crystallize, and thus the final formulation does not dry out or cause the tube cap to lock to the nozzle.

Surfactant

The primary purpose of a surfactant in toothpaste is to create a foam while the teeth are brushed. This foam provides an enjoyable sensation. Secondarily, the surfactant helps remove material dislodged by the toothbrush, and it may have minor effects on plaque accumulation.

The surfactant most commonly used is the anionic detergent sodium lauryl sulfate. Other surfactants that have been used include sodium dodecylbenzene sulfonate [CAS: 25155-30-0], sodium *N*-lauroyl sarcosinate or Gardol [CAS: 137-16-6], and sodium cocomonoglyceride sulfonate [CAS: 3694-90-4]. Cationic and nonionic surfactants are not used for several reasons, including incompatibility with the abrasive system and lack of high foaming capability. See also **Surfactants**.

Binding and Thickening Agents

The rheological properties of a dentifrice are primarily determined by the agent used to bind and thicken the product and allow its extrusion as a firm, but easily dispersible, ribbon. A well-formulated toothpaste exhibits a high yield point and thixotropy, that is, it is easily liquified. Gums and resins are employed to obtain the desired thickening and binding. Each has a characteristic rheological spectrum and lends structure to the toothpaste accordingly. Gums and resins widely used include acrylic acid polymers, carrageenan [CAS: 9000-07-1], sodium carboxymethyl cellulose [CAS: 9004-32-4], xanthan gum [CAS: 11138-66-2], and hydrated silica [CAS: 10279-57-9]. Each is available in several variations having different properties. Selection of an optimal gum or resin along with the selection of appropriate other ingredients results in a paste that extrudes with the application of minimal pressure to form a smooth, cohesive ribbon, which stands up on the toothbrush bristles and breaks down and disperses quickly in the mouth during brushing.

Color

Colorants used in dentifrices are regulated by the Food and Drug Administration. They are FD&C (food, drug, and cosmetic) or D&C (drug and cosmetic). See also **Colorants (Foods)**.

Special Active Agents

Toothpastes are vehicles for agents that provide special therapeutic and nontherapeutic effects. The scope of these agents has increased dramatically since the 1960s and research continues.

Fluoride added to a compatible dentifrice base at a level of 1000 ppm has been clinically proven to reduce the incidence of dental caries by about 25% on average, even in areas where the water supply is fluoridated. Elevation to 1500 ppm increases the protection. Sources of fluoride approved for use in dentifrices are sodium fluoride [CAS: 7681-49-4] (0.22%), sodium monofluorophosphate (0.76%), and stannous fluoride [CAS: 7783-47-3] (0.41%). The Food and Drug Administration regulates fluoridated dentifrices as drugs and has established parameters for safe and effective products. Compatibility of the fluoride with the abrasive is an important requirement. See also **Fluorine**.

Several agents delivered via toothpaste inhibit the accumulation of dental calculus. Pyrophosphate salts, with or without a methoxyethylene–maleic acid copolymer, and zinc salts have given positive results in clinical trials. Pyrophosphates were added as potassium or sodium pyrophosphate or mixtures at a level of about 2–6%. The zinc salt was zinc citrate [CAS:

546-46-3] (0.5–2.0%) or zinc chloride [CAS: 7646-85-7] (2.0%). The products all contained fluoride in addition to the calculus inhibitor. The anticaries activity of the fluoride was not compromised.

Dentifrices are also vehicles for agents that alleviate dentinal hypersensitivity. Among the materials that have given positive results in clinical tests are potassium nitrate [CAS: 7757-79-1] (5%) and strontium chloride [CAS: 10476-85-4] (10%).

An antimicrobial agent that reduces dental plaque and can be delivered effectively from toothpaste is a combination of Triclosan [CAS: 3380-34-5] (0.2% in the toothpaste) and zinc citrate (0.5%). This agent influenced plaque accumulation and reduced the incidence of gingival bleeding in clinical tests. Additional dentifrices for improved gingival health are in the offing.

Claims for safety and efficacy of therapeutic dentifrices are regulated by the Food and Drug Administration. The Council on Dental Therapeutics of the American Dental Association reviews products and grants a Seal of Acceptance to those products deemed worthy.

Specific Toothpaste Formulations

Two types of toothpaste formulation predominate. Type 1 is a low abrasive — high solvent toothpaste (Table 1); type 2 is a high abrasive — low solvent toothpaste (Table 2). The most important differences are the ratio of humectant to abrasive and the nature of the abrasive. Type 1 dentifrices were introduced nationally to the U.S. market in 1970 and now constitute the predominant type. Type 2 dentifrices represent a popular earlier formulation, in which economic and scientific considerations related to the abrasive and humectant favored use of a maximum amount of the abrasive component. All type 1 dentifrices of the early 1990s contain an amorphous hydrated silica powder as the abrasive. Type 2 dentifrices may contain one or more of many insoluble minerals.

Gels

Amorphous hydrated silicas of a purity and structure typical of those used in type 1 dentifrices and the liquid portion (humectant system) of type 1 dentifrices both have approximately the same refractive index, ie, about 1.47. As a result, the type 1 dentifrices represented in Table 1 are inherently transparent or translucent. In the marketplace it has become popular to refer to such dentifrices as gels. For marketing reasons some companies have chosen to opacify these products, with titanium dioxide, for example. The opacified products are identical in functionality, structure, and all other ways, except opacity, to their translucent or transparent counterparts.

TABLE 1. TYPE 1 DENTIFRICES

Function	Ingredient	CAS Registry Number	Amount, %
Abrasive	Silica xerogel (hydrated silica)	[10279-57-9]	14.00
Humectant system	Sorbitol, 70%	[50-70-4]	46.72
	Glycerol, 96%	[56-81-5]	20.90
	Poly(ethylene glycol) 1450	[25322-68-3]	5.00
Surfactant	Sodium lauryl sulfate	[151-21-3]	1.50
Binder and thickener	Carboxymethylcellulose, grade 9MX	[9004-32-4]	0.30
	Silica aerogel	[7631-86-9]	8.00
Flavor	Flavor oils		2.00
	Sodium saccharin		0.20
Preservative	Sodium benzoate	[532-32-1]	0.10
Anticaries agent	Sodium monofluorophosphate	[10163-15-2]	0.78
Color solution	FD&C, D&C dyes in water		0.50

TABLE 2. TYPE 1 DENTIFRICES

Function	Ingredient	CAS Registry Number	Amount, %
Abrasive	α-alumina trihydrate	[12252-70-9]	55.0
Humectant system	glycerol	[56-81-5]	20.0
water	[7732-18-5]	21.6	
Surfactant	sodium lauryl sulfate	[151-21-3]	1.5
Binder and Thickener	sodium carboxymethylcellulose	[9004-32-4]	1.0
Flavor	flavor oils		0.9

Dental Rinses

Dental rinses, as discussed here, do not include gargles and other liquids that are indicated for inflammation and diseases of the throat and are unrelated to dental plaque.

The primary function of a dental rinse is to clean and refresh the mouth. With few exceptions dental rinses also fulfill important secondary functions. Some contain agents that inhibit or destroy oral microbial populations that aid in generating dental plaque or oral malodor. Other rinses deliver fluoride to the teeth to prevent the development of caries. A relatively new rinse is used before toothbrushing to enhance the efficacy of brushing. Dental rinses can also deliver active agents that cannot be provided by toothpaste because of chemical incompatibility between the agent and the toothpaste ingredients. For example, sodium fluoride and calcium-containing abrasives are incompatible, as are sodium lauryl sulfate (an anionic detergent) and chlorhexidine [CAS: 55-56-1] (an active cationic antimicrobial agent).

The amount of a product introduced into the oral cavity is substantially greater with a dental rinse than with a dentifrice, the action of swishing the rinse assures thorough distribution of the agent to accessible oral surfaces.

An oral dental rinse generally consists of water, alcohol, a humectant, an emulsifier, flavor, color, and an active agent. Water is the primary vehicle. The alcohol provides bite and is also a formulation aid. The humectant improves the feel in the mouth and also prevents locking of the cap to the container between uses; glycerin or noncrystallizing sorbitol may be satisfactory. The emulsifier is a nonionic type, for example, a polyoxyethylene–polyoxypropylene block copolymer or a polyoxyethylene sorbitan fatty acid ester. Flavors are generally a type of mint or cinnamon. Colors are FD&C or D&C.

Active agents vary according to use. For controlling bad breath, zinc salts, sodium lauryl sulfate, and flavors are used. To destroy oral microorganisms, chlorhexidine, cetylpyridinium chloride [123-03-5], and benzalkonium chloride [68391-01-5] are valuable. Essential oils, such as thymol [89-83-8]; eucalyptol [470-82-6]; menthol, and methyl salicylate [119-36-8] reduce plaque-related gingivitis. See also **Oils, Essential**. Sodium fluoride aids in caries control.

Chlorhexidine is the most potent oral antimicrobial agent available. It has side effects and is sold only with a prescription. It is active delivered from a rinse, but a compatible toothpaste vehicle for chlorhexidine has yet to be developed.

A dental rinse containing sodium lauryl sulfate, marketed to be used before toothbrushing, removes some plaque directly and makes residual plaque easier to remove by brushing.

Claims for oral dental rinses are regulated by the Food and Drug Administration whether they are marketed as drugs or cosmetics. The Council on Dental Therapeutics of the American Dental Association reviews oral rinses, and may authorize use of the Seal of Acceptance for a product.

Tooth Whitening Agents

Tooth whitening preparations are available by dentist's prescription and over the counter. Many products are marketed as systems comprising toothpastes and treatment pastes or gels. The whitening agent in most is 10% carbamide peroxide [35220-04-3], which reacts with water to release hydrogen peroxide. The hydrogen peroxide liberates free-oxygen radicals, which bleach the dental enamel. Some preparations contain calcium peroxide [1305-79-9] as the bleaching agent. See also **Bleaching Agents**. The products have undisputed efficacy. Some dental authorities have questioned their safety, hypothesizing that long-term chronic exposure to hydrogen peroxide can result in ill effects. However, human clinical trials to substantiate this hypothesis have not yet been forthcoming, and appropriately formulated and tested whitening products must be considered safe when used in accordance with directions.

DENTITION. The form and arrangement of the teeth in vertebrates. Teeth are so intimately related to the food that they are involved in the fundamental adaptations of the animal. In connection with the study of the many adaptations of teeth, terms have been coined which apply in some cases either to the tooth itself or to the entire dentition, while others apply to the dentition in general.

The primitive form of tooth is apparently that of the sharks, which has a principal sharp flattened point and in some cases fairly prominent lateral points. These teeth are arranged in several rows and are renewed as needed. In other fishes and in the amphibians teeth are also developed in large numbers and in some forms occur elsewhere in the mouth than on the jaws. They are named for the part of the skull with which they are associated, as the vomerine teeth.

In the reptiles and mammals the simpler condition of a row of teeth along each jaw prevails. The teeth may be entirely conical, as in the reptiles, or of various types, as in the mammals, and may be indefinitely renewable or limited to one or two sets. Where teeth are of more than one kind the dentition is said to be heterodont. The forms of teeth include the sharply conical canines, the sharp-edged cutting incisors, and the broad grinders, which include premolars and molars. Renewal is unlimited in the reptiles but in the more highly specialized mammals only one or two sets appear normally. Monophyodont dentition consists of one set and diphyodont includes a temporary set of milk teeth which is replaced by a set of permanent teeth, as in humans.

The numbers of teeth of different kinds are expressed in a dental formula as a distinctive characteristic of mammals. In this formula the teeth of one-half of each jaw are listed in this order: incisors, canines, premolars and molars, and those of the upper jaw are placed above those of the lower jaw. Thus the dental formula of man is 2123/2123 and that of the woodchuck is 1023/1013. The zeros in the latter formula indicate the absence of canines.

The position of the teeth in the jaw is also sometimes indicated by a special term. When placed along the edge of the jawbone the dentition is said to be acrodont, and when placed along the inner margin, pleurodont.

DEOXIDIZING AGENT. A compound that has an affinity for oxygen — hence, chemically removes oxygen from many substances. In essence, a deoxidizing agent plays the role that is reverse that of an oxidizing agent. Thus, a deoxidizing agent is a reducing agent. Of course, at one time, oxidation meant simply a combination with oxygen and reduction meant a loss of oxygen. In their broader interpretations, oxidation now refers to the loss of one or more electrons from the outer-shell of an atom, and the reverse for reduction. Although the broader interpretation also could apply to deoxidation, the term still is interpreted generally as removal of oxygen.

Oxygen frequently is an impurity in various metallurgical processes, particularly melting and refining processes. Deoxidizing agents are commonly used to reduce or remove oxygen from molten metals. Lithium metal, for example, will preferably absorb oxygen (by combination) from copper and copper alloys. Boron carbide also is used as a deoxidizing agent for casting copper. Silicon usually in the form of ferrosilicon, and manganese in the form of ferromanganeses are widely used in the production of steel and iron alloys. Aluminum, titanium, zirconium, and vanadium also play a deoxidizing part in the production of iron alloys. Magnesium is also a powerful deoxidizer and desulfurizer and is used in the production of such metals as beryllium, hafnium, titanium, uranium, yttrium, and zirconium. Zinc is used as a deoxidant in the refinement of silver and gold.

Normally, the process of rock formation is one of oxidation. However, a greenish or yellowish area in a red rock may be developed by reduction (deoxidation) of ferric oxide in the presence of organic materials.

Deoxidation also enters into physiological reactions. For example, ascorbic acid (vitamin C) is acclaimed as an antioxidant.

DEOXYRIBONUCLEIC ACID (DNA). A complex sugar-protein polymer of nucleoprotein which contains the genetic code for enzymes in the cell. It occurs as a major component of the genes, which are located on the chromosomes in the cell nucleus. The DNA molecule is a unique and vastly intricate structure; it is comprised of from 3000 to several million nucleotide units arranged in a double helix containing phosphoric acid, 2-deoxyribose, and the nitrogenous bases adenine, guanine, cytosine, and thymine. The spiral consists of two chains of alternating phosphate and deoxyribose units in continuous linkages. The nitrogenous bases project toward the axis of the spiral and are joined to the chains by hydrogen bonds. Adenine always unites with thymine and cytosine with guanine. The complementarity of the bases on the joined chains allows each chain to act as a template for replication of the other when the chains are separated, thus producing two new strands of DNA. The sequence of the bases on the chains varies with the individual, and it is this sequence that governs the genetic code. DNA works in conjunction with ribonucleic acid (RNA).

The foregoing is a highly generalized definition. Within the last few years, considerable new knowledge has been gained concerning DNA and its genetic function. The early studies of genes concentrated on bacterial genes. In these, the bacterial genes are not spread out in pieces. More recent studies in the mid- and late 1970s concentrated on animal viruses, animals, and humans. The genes in these cases, with the possible exception of the histone genes, are found in pieces that are spread out along DNA. Thus, between gene fragments, there are long stretches of DNA, the functions of which are poorly understood as of the present. This discovery of fragmented or spaced out genes in animals raised the question as to whether such structures are exceptional or the rule. Subsequent research has indicated that they are the norm.

This discovery, while creating several new and fundamental questions, has provided at least partial answers to some former questions. For example, it has been known for some years that there are large quantities of DNA in the cells of higher organisms, that is, DNA in an amount far in excess of the DNA required if the genes were not in pieces. The spacing out of the genes into fragments accounts for all or part of the excess DNA previously noted.

As of the early 1980s, numerous hypotheses have been formulated by molecular biologists and this fundamental discovery has stimulated a whole new line of research in many laboratories throughout the world. Some scientists have observed that the extra DNA cannot be accounted for simply upon the basis of evolutionary theories. The extra DNA may play a role in controlling gene expression. The complexity and current uncertainty of these hypotheses are beyond the scope of this book at this juncture in the research program. Perhaps the topic will be better clarified at the time of the next edition. Several of the references listed shed further insights.

Studies of DNA in the human cell have suggested that the intricate DNA structure may be as much as 1.2 meters (4 feet) long — and yet it is contained within a nucleus which is less than 0.025 millimeters ($\frac{1}{1000}$ inch) in diameter. That the DNA structure is in the form of a complex tangle under these conditions is not difficult to imagine. Upon division of the cell, the DNA condenses into strands in duplicate copies, one set for each daughter cell. It follows that the copying must take place while the DNA is in the form of a tangle, but in such a manner to allow easy separation of the duplicate copies. The mechanics and time required for the copying process still remain undetermined. As early as 1974, Berezney and Coffey (Johns Hopkins University School of Medicine) estimated from electron micrographs that about 5% of the protein in a nucleus appears to be a rigid skeleton or scaffolding, a structure they termed the *nuclear matrix*. These researchers have proposed that the DNA in the nucleus is attached onto the nuclear matrix at thousands of sites, with the genetic material arrayed in thousands of loops. The loops pass through enzyme complexes located at the matrix sites and in so doing are copied. In the process, the loops are preserved and remain attached to the matrix. It is further postulated that when a cell divides, duplicate copies of loops already joined to a scaffolding are drawn apart to the daughter cells. It has been estimated that genetic material in rat liver cells consists of from 10,000 to 15,000 loops. Thus, the nuclear matrix would have a corresponding number of enzyme complexes.

DEPARTURE (Navigation). Any course and distance covered by a ship may be resolved into two components at right angles to each other. One of these components will be parallel to a meridian; the other will be along a parallel of latitude, and is known by the term departure. If the lengths of these components are expressed in nautical miles, the component along the meridian may be immediately converted into difference of latitude, because a minute of arc of latitude is practically equal to one nautical mile. The component along the parallel of latitude, expressed in nautical miles and referred to as easting or westing, is known as the departure.

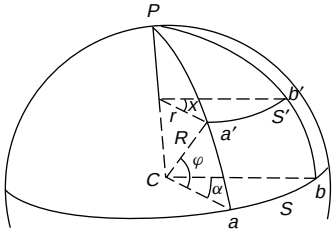

Fig. 1. Analysis of components in converting departure into difference of longitude.

For the solution of various problems in dead reckoning and in the sailings, it becomes necessary to convert departure into difference of longitude. Figure 1 illustrates the problem. Here, we have S', a departure measured along the parallel of latitude ϕ between the meridians $Pa'a$ and $Pb'b$. The arc, S, of the equator represents the difference of longitude corresponding to the departure S'. Planes are passed through S' and S perpendicular to the axis of the earth, PC, and radii are drawn in these planes to include the angles subtended by S' and S . Call R the radius of the earth and r the radius of the arc S'. The angles subtended by S and S'. must be equal, and we have at once $S/R = S'/r$. By the definition of latitude (assuming the earth as spherical), we have the plane angle $aCa' = \phi$ and, from the definition of the trigonometric functions, $R/r = \sec\phi$. Therefore, we have $S/S' = R/r = \sec\phi$, or $S = S'\sec\phi$. Since S' is expressed in nautical miles, which are practically equivalent to a minute of arc on the equator, we have at once $S = S'\sec\phi$ as the difference in longitude corresponding to the departure S', the difference in longitude being thus expressed in minutes of arc.

DEPHLEGMATION. Partial condensation of vapor from a distillation operation to produce a liquid richer in higher-boiling constituents than the original vapor. The residual vapor is richer in the lower-boiling constituents.

See also **Distillation**.

DEPOLARIZATION. This term designates any process of removing polarization. Representative examples include the following:

1. Depolarization of an electric cell, most commonly a dry cell, is commonly effected by a substance added to the cell that prevents the accumulation of reaction products that interfere with the function of the cell. A related purpose may be accomplished by a diaphragm placed in the cell so as to prevent mixing of the reaction products. Such added substances and diaphragms are often called depolarizers, the latter sometimes being called an electrical depolarizer.

2. An optical depolarizer is a device for the resolution of polarized light, to which process the term depolarization may be applied.

3. Electric depolarization or demagnetization may be effected by a depolarization field. When an electric or magnetic field is applied to a macroscopic specimen, the field acting on a given atom contains a contribution due to the charges or poles induced on the surface of the specimen. This field opposes the external applied field, and hence tends to reduce the polarization of the material. See also **Demagnetizing Field**.

4. Biological depolarization is a decrease in the membrane potential (i.e., the potential across the cell membrane).

DEPOLARIZATION (Battery). See **Batteries**.

DEPOSITION. Processes by which traces gases or particles are transferred from the atmosphere to the surface of the earth. Atmospheric deposition is usually divided into two categories, wet deposition and dry deposition, depending on the phase of the material during the deposition process. Thus, in wet deposition, the gas or particle is first incorporated into a droplet and is then transferred to the surface via precipitation. In dry deposition, the gas or particle is transported to ground level, where it is adsorbed onto a surface. The surface can be the ocean, soil, vegetation, buildings, etc. Note that the surface involved in the dry deposition may be wet or dry — the "dry" in dry deposition refers only to the phase of the material being deposited.

DEPRESSED POLE. The celestial pole below the horizon, of opposite name to the latitude. The celestial pole above the horizon is called the *elevated pole*.

DEPRESSION (Meteorology). See **Atmosphere (Earth)**.

DEPTH MEASUREMENT (Underwater). See **Sounding**.

DEPTH OF FIELD. In photography, the term depth of field refers to the distance over which satisfactory definition is obtained when the lens is in focus for a certain distance. If, for example, a lens is in focus for an object at a distance of 25 feet and the definition is satisfactory on objects from 20–40 feet, the depth of field extends from 20–40 feet. Depth of field is frequently but incorrectly termed depth of focus, which is the range of image distances corresponding to the range of object distances covered by the depth of field.

The depth of field depends upon: (1) the standard adopted for "satisfactory" definition; (2) the distance of the plane on which the lens is in focus; (3) the focal length of the lens; (4) the relative aperture (f/number). So far as the last three are concerned, we may note (1) that the depth of field increases with the distance of the plane on which the lens is in focus and (2) that it becomes less as the focal length or (3) as the aperture increases.

Let O_3, O_2, O_1 represent an object, parts of which are at different distances from the lens L. Suppose the lens to be focused on O_1, a point image I_1 will be formed on the focusing screen, or sensitive plate. With the focusing screen, or the sensitive plate, at this point it is clear that the image of O_2 is formed at I_2 *behind* the screen and that of O_3 at I_3 in *front* of the screen. In other words, the position of the image point varies with the distance of the object point and the lens cannot produce a point for point image upon a plane surface, such as the sensitive film, unless

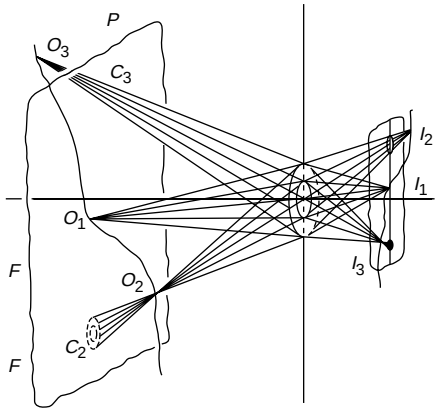

Fig. 1. Demonstration of depth of field.

the subject itself is a plane. When this is not the case, the image of points nearer or further from the lens is a circular disk rather than a point. See Fig. 1.

Any disk, however, will appear to the eye as a point if the viewing distance is sufficiently great. At a distance of 10 inches, for example, a circle with a diameter of $\frac{1}{100}$ inch appears as a point to the average eye. On an angular basis this corresponds to about 2 minutes of arc.

Since any unsharpness in any part of the negative is increased when an enlargement is made, the disk, or circle of confusion, in an enlargement is equal to the diameter of the disk in the negative multiplied by the degree (times) of enlargement. Thus, if the largest circle allowable for sharp definition is assumed to be $\frac{1}{100}$ inch, and the print is a $5\times$ enlargement, the maximum diameter of the circle of confusion in the negative is $\frac{1}{100}\times\frac{1}{5}$ or $\frac{1}{500}$ inch, and the depth of field should be calculated accordingly.

If it is assumed that the viewing distance is the distance at which the proper perspective is obtained, i.e., a distance equal to the focal length of the lens, then the circle of confusion can be expressed as a fraction of the focal length of the lens. The value generally used is 0.00058 or $\frac{1}{1720}$ of the focal length. If

$u =$ distance focused on,
$\theta =$ angular size of circle of confusion ($\frac{1}{1720}$ of the focal length),
$\tau =$ effective diameter of lens or the focal length divided by the f/number.

then the nearest point sharply defined in front of the plane in focus is

$$\frac{u^2\tan\theta}{\tau + u\tan\theta}$$

and the greatest distance beyond the plane in focus is

$$\frac{u^2\tan\theta}{\tau + u\tan\theta}$$

Tables of depth of field are included in most camera manuals and in reference books.

DERECHO. The word "derecho" is of Spanish origin, and means straight ahead. The strict translation of this word leads to the general public's understanding of a derecho: any straight-line wind associated with a thunderstorm. While correct to a certain extent, a more technical definition of derecho is a widespread convectively produced wind event resulting from the outflow boundary of a mesoscale convective system (MCS, see below). Thus, derecho producing mesoscale convective systems are referred to as DMCSs. The winds associated with derechos blow straight ahead, or are straight-line. The term straight-line is meant to be a contrast to the rotating winds associated with tornadoes.

Types of Derechos

There are three types of derechos:

Progressive derechos are common in the spring and summer, as progressive derechos depend very little on strong synoptic or dynamic forcings. Instead, these derechos feed on the abundant potential energy available in the lower levels of the atmosphere during the late spring and summer, and are dependent on instability. In addition, it was found that almost all progressive derechos form on the cool side of a pseudo-stationary front. Evidence for the existence of a progressive derecho can be found on the radar imagery, as progressive derechos produce the "bow echo," a term introduced by Fujita in 1978 often associated with derechos.

Serial derechos, unlike progressive derechos, form under conditions of strong synoptic and dynamic forcings. Generally, serial derechos are associated with low-pressure systems, where the dynamic lifting caused by the low, and associated fronts, produces an environment conducive for the genesis of MCSs. Serial derechos do not require the amount of instability necessary for genesis of a progressive derecho, but the environment must be unstable enough to support convection. While progressive derechos are confined to the warm season, serial derechos can happen at any time throughout the year, because of the consistent cycle of low-pressure systems in the mid-latitudes. In fact, cool season derechos, are predominantly serial derechos, as the cool season atmosphere does not possess sufficient potential energy for progressive derechos, yet when combined with synoptic forcings, are unstable enough to sustain the convection.

Hybrid derechos have characteristics of a serial and progressive derecho. These types of derechos are associated with a deep low like serial derechos, but are relatively small in size like progressive derechos.

According to the National Weather Service criterion, a derecho is classified as a band of storms that have winds of at least 50 knots (58 mph or 93 km/h) along the entire span of the derecho.

Mesoscale Convective Systems

Mesoscale convective systems are clusters of thunderstorms not meeting the size or time criteria of mesoscale convective complexes (MCC). MCCs are identified by criteria verified on IR satellite images. To become a MCC, a system must have a cloud shield greater than 100,000 square kilometers (38,610 square miles), with cloud top temperatures less than -32 °C (-26 °F). The interior of the system must be greater than 50,000 square kilometers (19,305 square miles), with cloud top temperatures less than -52 °C (-62 °F), as determined from IR satellite images. These size conditions must be met for 6 hours in order to qualify as a MCC. Additionally, at the time of maximum extent, the cloud shield must have an eccentricity (minor axis/major axis) of greater than or equal to 0.7. So, a MCC is a MCS that has met these criteria. Therefore, a MCS is often smaller or shorter lived than a MCC. As defined by the National Weather Service, MCSs still must meet certain temporal and spatial requirements. In order for the National Weather Service to label a system as a MCS it must have a continuous area of cloud top temperatures below -52 °C (-62 °F), that is at least 250 kilometers (155 miles) in length, and lasts for no less than three hours.

Basically, MCSs are self-sustaining, large thunderstorm clusters. Once an MCS is formed, it can feed off of itself, and specifically its outflow boundary, to generate new individual storms within the MCS. This self-sustenance and regeneration process accounts for the long life span of a MCS. A typical thunderstorm lasts about one hour, and an isolated supercell can last two to three hours, but it is not uncommon for MCSs to exist for ten hours. In a study of cool season derechos, it was found that the average duration for cool season DMCSs was 8.8 hours, which is considerably longer than the life-span of an isolated thunderstorm.

Potential Dangers

There are two dangers associated with derechos: 1) the duration of the damaging winds and 2) the spatial coverage of such winds. Damaging winds are classified as those winds exceeding 25–30 m/s, or 50–60 knots (57–69 mph). In derecho situations it is not uncommon for winds of this magnitude to last for over 30 minutes, with occasional gusts of 60–70 m/s. Derechos also, by definition, are widespread events, possibly affecting areas as large as 2,000 square kilometers (772 square miles). The area affected by derechos rivals the coverage area of a tropical storm, a parallel that places the magnitude of DMCSs in proper perspective. The potential danger of a derecho is immense because of the duration and spatial coverage of such events.

DERIVATIVE (Chemical). A term used in organic chemistry to express the relation between certain known or hypothetical substances and the compound formed from them by simple chemical processes in which the nucleus or skeleton of the parent substance exists. Thus, phenol, aniline, and toluene are said to be derivatives of benzene; and many of the terpenes are derivatives of cymene. Or, when a paraffin such as methane is halogenated, a series of halogen-substitution products may be formed. Depending upon conditions of the reaction, CH_4 plus Cl may yield the monosubstitution product CH_3Cl (methyl chloride), or the disubstitution product CH_2Cl_2 (methylene dichloride), or the trisubstitution product $CHCl_3$ (chloroform), or the tetrasubstitution product CCl_4 (carbon tetrachloride). In essence, these compounds are derived from methane and thus are methane derivatives as the result of chlorination. Usually the term applies to those compounds where the resulting compound is formed in one step, although a chain of steps may be involved in some cases, depending essentially upon how easy it is to identify the "derivative" with the parent substance. Where a chain of steps is involved, the intervening compounds often are called intermediates rather than derivatives.

DERIVATIVE (Mathematics). The instantaneous rate of change of a function with respect to its independent variable. Let $y = f(x)$ be a given function of its independent variable x, and for an assigned value of x consider a small increase or increment of it, Δx. The dependent variable increases simultaneously by Δy where $\Delta y = f(x + \Delta x) - f(x)$. The ratio of increments is

$$\frac{\Delta y}{\Delta x} = \frac{f(x + \Delta x) - f(x)}{\Delta x}$$

and, by definition, the limit of the right-hand member when $\Delta x \to 0$ is the derivative of $f(x)$, or

$$\frac{dy}{dx} = \lim_{\Delta x \to 0} \frac{f(x - \Delta x) - f(x)}{\Delta x} = \lim_{\Delta x \to 0} \frac{\Delta y}{\Delta x}$$

If the limit exists the function is continuous; if the limit fails to exist at one or more values of x these are said to be singular points for the function.

The process of finding the derivative of a function is differentiation. The usual symbol for a derivative is dy/dx but y', $f'(x)$ and other designations are also used. If the function $y = f(x)$ is plotted in rectangular coordinates, the slope of the curve at the point $x = x_0$ is its derivative, dy/dx, at that point.

The derivative of the derivative of a function is a higher derivative or one of higher order. The derivative of the second order is written in various forms, thus: d^2y/dx^2, $D_x^2 y$, $f''(x)$, f_{xx}, y''. Similar notation is used for derivatives of third or higher order. In general, the nth derivative is the derivative of the $(n-1)$th derivative and it could be designated as $d^n y/dx$, $D_x^n y$, $f^{(n)}(x)$, or $y^{(n)}$.

Let $u = f(x, y, z, \ldots)$ be a function of several variables. Keep all of the variables constant except one, x for example, and give x an increment Δx. If Δu is the corresponding increment in u, then the limit $\lim_{x \to 0} \Delta u/\Delta x$ is the partial derivative of u with respect to x. It is denoted by $\partial u/\partial x$, u_x, or, especially in thermodynamics, by $(\partial u/\partial x)y, z, \ldots$ where the subscripts indicate the variables held constant during the differentiation. The partial derivatives $\partial u/\partial y$, $\partial u/\partial z$, etc., are defined similarly.

In general, the partial derivatives are themselves functions of one or more or the variables. They may thus be differentiated again to obtain partial derivatives of higher order:

$$\frac{\partial^2 u}{\partial x^2} = \frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x}\right); \quad \frac{\partial^2 u}{\partial x \partial y} = \frac{\partial}{\partial x}\left(\frac{\partial u}{\partial y}\right)$$

$$\frac{\partial^2 u}{\partial y \partial x} = \frac{\partial}{\partial y}\left(\frac{\partial u}{\partial x}\right); \quad \frac{\partial^3 u}{\partial x^3} = \frac{\partial}{\partial x}\left(\frac{\partial^2 u}{\partial x^2}\right); \text{ etc.}$$

The abbreviated notation u_{xx}, u_{xxx}, etc., is often used.

If the first partial derivative of a function is continuous, $u_{xy} = u_{yx}$. In this case, if each variable is itself a function of a single independent variable t, then one can write.

$$\frac{du}{dt} = \frac{\partial u}{\partial x}\frac{dx}{dt} + \frac{\partial u}{\partial y}\frac{dy}{dt} + \frac{\partial u}{\partial z}\frac{dz}{dt} + \cdots$$

which is the total derivative.

A directional derivative is one that gives not only the rate of change of a function but its direction of change. It is most conveniently discussed by the methods of vector analysis.

DERMAPTERA *(Insecta).* The earwigs. An order of insects made up of species whose forewings, when present, are short leathery wing covers, and whose abdomen bears a pair of appendages like the jaws of a forceps at the tip. The common name is based on the supposition that they enter the ears of human beings. They are plant-eating, insect-eating, and probably in some species scavengers.

DERMATITIS AND DERMATOSIS. *Dermatitis* is an inflammation of the skin and is a term frequently used erroneously as a synonym for *dermatosis*, which means skin disease. Seemingly, there are almost unlimited numbers of disorders which may affect the skin, so that the field in medicine which is concerned with the skin and its disorders and diseases, dermatology, is broad and complex.

The symptoms of dermatitis are varied, and include reddening (*erythema*), small blisters, crusting, oozing of fluids, scaliness, cracking or fissuring, and other secondary changes from the normal appearance. The causes of these conditions are many, and include burns, physical irritants, infections, plant and insect poisons, strong chemicals (industrial), nutritional deficiency, disturbances of other parts of the body, and systemic diseases.

The word *eczema* is an older and less preferred term for *dermatitis*. However, eczematous dermatitis sometimes is used to describe vesicular dermatitis.

Some of the most common skin disorders are described separately in this *Encyclopedia*. Refer to list of articles at the end of this entry.

Mechanical Irritants

Skin changes may result from scratching or picking at the skin with fingernails or other objects, or from irritation of the skin by the chafing of clothing. Bedsores on invalids are caused by such mechanical irritation, and can be prevented by proper nursing techniques. Rubbing the skin over a long period of time may cause it to assume a permanent thickened and leathery appearance. When two surfaces of the skin touch each other, such as between the thighs, and cause friction, a resulting inflammation may develop. This condition is known as *intertrigo*, and may be accompanied by cracking, oozing, burning, and itching. Such lesions frequently are complicated by infection, either by yeasts, bacteria, or both, and require attention.

Corns are hard, cone-shaped, thickened areas of the skin which usually appear on the toes as the result of friction or pressure from improperly fitting shoes or socks. The inner portion of the corn is pointed, so that external pressure forces the point of the corn into the underlying tissues with a painful effect. Calluses resemble corns, except that they cover larger areas and have no pointed central core.

Viral Infections

Many cases of dermatitis are caused by viral agents that either infect the skin or invade the body as a whole and cause symptoms of dermatitis. The source of these disorders determines whether the skin itself is the site toward which attention should be directed, or whether medical care must be given to the body as a whole.

Warts. These epidermal proliferations are caused by the human papilloma virus and affect up to about 10% of the young adult population. Transmission can be by direct skin contact. Some 60 subtypes of human papilloma virus have been identified, some of which are associated with cancerous and precancerous conditions. See also **Wart (Verrucae)**.

Herpes Simplex Virus (HSV). Of medium size (diameter of 180 nm), the viral envelope contains an icosahedral nucleocapsid that encloses double-strand DNA. There are two types of HSV. Type 1 is associated with *fever blisters* (cold sores), which are common and most frequently occur in children of the 1-to-5 age group. However, the condition is quite common among adults as well. The virus is believed to be dormant in body tissues, becoming active only in the presence of a trigger mechanism, such as an upper respiratory tract infection, fever, menstrual period, physical or emotional stress, over-exposure to sunlight, or as an allergic reaction to some foods and drugs. The lesions usually take the form of small blisters, the base of which may be reddened. The most common site is the lip, but eruptions also may occur on the nose, face, ears, genitals, tongue, or any mucous membrane. A fluid exudes from the sores and forms a crust, which eventually flakes off. Occasionally, there may be swelling of the lymph nodes in the areas near the sore. The condition usually disappears spontaneously within one to two weeks, but it is not uncommon for it to recur. Although the infection rarely is severe, an infection of the cornea of the eye, when not promptly treated, can result in permanently impaired vision.

Type 2 HSV affects the genitalia and is ranked high on the list of common venereal diseases. Type 2 also appears as an opportunistic anal or perianal infection in AIDS and in immunocompromised hosts who have received an organ transplant. Severely immunocompromised patients may develop widespread lesions that may not heal for several months. During the course of Type 2 infections, most patients will develop new lesions after the initial infection. Extragenital lesions of the fingers, extremities, lip, groin, buttock, or eye may develop. Fungal infection may be a concurrent complication. Neonatal infection occurs in approximately 1 in 7500 births. See also **Sexually Transmitted Diseases**.

Varicella-Zoster Virus (VZV). Varicella-zoster virus closely resembles HSV. The two principal diseases attributable to VZV are chicken pox and zoster (shingles). See also **Chickenpox (Varicella)**.

Shingles usually is preceded by fever and malaise that may persist for 4 to 6 days, after which papules surrounded by an erythematous base appear. These are located along the path of the infected ganglion (mass of nerve cells) or ganglia. In about 5 days, the papules dry and crust. Some authorities postulate that spinal sensor ganglia that may have been infected years earlier (chicken pox) may cause reinfection during a period of low host resistance. Neuritic pain frequently occurs when the infection spreads to the skin. This usually accompanies the rash of acute zoster. Neuralgia may persist for an extended period after the disease has been arrested or spontaneously ceases. Treatment is mainly supportive. The physician must be on guard to prevent superimposed bacterial infection, usually requiring the administration of antibiotics.

Bacterial Infections

Dermatitis from bacterial infections may be caused by (1) bacteria which are located in the skin itself, (2) bacteria which are distributed in the skin and other parts of the body, or (3) bacteria which are solely in other parts of the body. In many rather common infectious diseases, such as scarlet fever, brucellosis, pneumonia, typhoid fever, rheumatic fever, and meningitis, an eruption or rash may appear on the skin which is not caused by the bacteria, but by secondary effects which the organisms produce. Treatment of patients with these conditions involves the destruction of the bacteria that have invaded the body as a whole. Diseases of this type are discussed elsewhere in this volume. See, for example. **Acne Vulgaris**; and Seborrheic Dermatitis.

The most common of the bacterial skin infections are boils (furuncles). These are round, tender, reddened elevations on the skin which contain a central core filled with pus and bacteria, usually staphylococci. See also **Boils**.

A number of other pus-forming eruptions of the skin are not uncommon. Barber's itch or *sycosis vulgaris* is a typical example and is caused by an infection with staphylococci. The disease attacks primarily the hair follicles. In this manner, the disease may spread until it eventually affects the entire bearded region. See also **Folliculitis**. The condition should be distinguished from another form of barber's itch (*tinea barbae*), which affects the lower bearded regions below the jaw, and which is, in reality, ringworm.

Impetigo is a common disease of childhood, but also occurring in adults. Impetigo is a superficial skin infection that occurs in nonbullous and bullous (elevated lesions) forms. Beta-hemolytic streptococcus usually produces nonbullous impetigo. Coagulase-positive staphylococcus aureus usually causes bullous impetigo. See also **Impetigo**.

Erysipelas is a superficial bacterial skin infection that characteristically extends into the cutaneous lymphatics. This disease has been traced back to the Middle Ages where it was referred to as "St Anthony's Fire," named after an Egyptian healer who was known for successfully treating the infection. Historically, this infection occurred on the face and was caused by *Streptococcus pyogenes.* However, a shift in the distribution and etiology of the disease has occurred, with most erysipelas infections now occurring on the legs and with non−group A streptococci sometimes being identified as the etiologic agents. See also **Erysipelas (St. Anthony's Fire)**.

Anthrax, is an acute infectious disease caused by the spore-forming bacterium *Bacillus anthracis*. Anthrax most commonly occurs in wild and domestic lower vertebrates (cattle, sheep, goats, camels, antelopes, and other herbivores), but it can also occur in humans when they are exposed to infected animals or tissue from infected animals. See also **Anthrax**.

Diphtheria of the skin is rare, and in most cases is caused by infection of some pre-existing wound with the diphtheria organism, *Corynebacterium diphtheriae*. The usual symptoms are a false membrane and gray ulceration around the swollen edges of the infected area. Such infections, although they are quite small in extent, are almost invariably fatal if not given prompt medical care. Diphtheria immunization is helpful in preventing the occurrence of the disease. See also **Bacterial Diseases**; and **Diphtheria**.

Tuberculosis of the skin is more common in Europe than in North America. There are two distinct varieties. In one, the tubercle bacillus (*Mycobacterium tuberculosis*) can be found in the eruptions. This is true tuberculosis of the skin. The other form (*tuberculids*) has many of the characteristics of the true tuberculosis, but the bacillus usually does not occur in the sores. Tuberculin or tuberculin-like substances probably cause this allergic reaction. The treatment of this condition is like the treatment given individuals with tuberculosis. See also **Respiratory System**; and **Tuberculosis**.

Gangrene. When deep wounds or lesions become infected with certain types of bacteria, or when the circulation to some tissues is interrupted, gangrene may develop. "Gangrene" is the medical term for death of tissue (necrosis) in part of the body. It's a serious condition that requires immediate medical care. See also **Gangrene**.

Infectious Eczemoid Dermatitis. This disease starts with blisters that become infected. The blisters fill with pus, and eventually result in a crusted, oozing, itchy condition. Such symptoms are believed caused by a secondary infection on the underlying eczema. In another disorder called *nodular erythema or erythema nodosum*, a number of small nodular swellings occur on the shins and other parts of the legs. The reddened swellings, which seem to be below the surface of the skin, are tender for some time, but frequently recede spontaneously. Such a condition usually indicates there is an allergic response of the blood vessels of the skin to some bacterial infection. Causes include streptococcal infection, tuberculosis, rheumatism, septic sore throat, and sensitivity to drugs.

Pityriasis rosea appears to be feebly infectious, although the organism that causes it is unknown. It is usually mild, and is manifested by small salmon-colored patches, which eventually coalesce to cause larger pigmented areas. The individual patches are oval or circinate and covered with finely crinkled, dry epidermis, which often desquamates, leaving collaterate scaling. The condition largely affects the trunk and is more prevalent in young adults during spring and summer months. It may disappear spontaneously within a few weeks, but requires medical attention to distinguish it from a number of other more severe skin disorders. See also **Pityriasis**.

Plant and Animal Causes

Skin disorders that result from contact with various plants are largely allergic in nature. See also **Allergy**. A variety of small (some minute) insects and other animals cause severe skin eruptions by bites, stings, or burrowing into the skin.

Scabies. Scabies is an infestation of the skin with the microscopic mite *Sarcoptes scabei*, (about $\frac{1}{50}$th of an inch (1/2 millimeter) long). Infestation is common, distributed worldwide, affecting all races and socioeconomic classes in all climates. Scabies spreads rapidly under crowded conditions where there is frequent skin-to-skin contact between people, such as in hospitals, institutions, child-care facilities, and nursing homes. Signs and symptoms of scabies infestation include:

- Pimple-like irritations, burrows or rash of the skin, especially the webbing between the fingers; the skin folds on the wrist, elbow, or knee; the penis, the breast, or shoulder blades.
- Intense itching, especially at night and over most of the body.
- Sores on the body caused by scratching. These sores can sometimes become infected with bacteria.

Scabies is contracted by direct, prolonged, skin-to-skin contact with a person already infested with scabies. Contact must be prolonged (a quick handshake or hug will usually not spread infestation). Infestation is easily spread to sexual partners and household members. Infestation may also occur by sharing clothing, towels, and bedding.

Sarcoptes scabiei, human itch or mange mites, are in the arthropod class Arachnida, subclass Acari, family Sarcoptidae. The mites burrow into the skin but never below the stratum corneum. The burrows appear as raised serpentine lines up to several centimeters long. Other races of scabies may cause infestations in other mammals such as domestic cats, dogs, pigs, and horses. It should be noted that races of mites found on other animals may establish infestations in humans. They may cause temporary itching due to dermatitis but they do not multiply on the human host.

These mites live on the surface of the skin, but the female burrows into the skin to lay its eggs (Fig. **1**). During this process the mite may remain under the skin for some time, traveling along and creating an extended tunnel in which the eggs are laid. The young develop in a few days, and then come directly to the surface where they spend their lives until they, in turn, are ready to lay eggs. The typical sign of scabies is the short, winding burrow in the skin, most often between the fingers and toes. In children, this may be accompanied by tiny blisters on the surface of the skin near the burrow. In this stage of the dermatitis, there is very little itching. Later, the skin may develop an allergy or hypersensitivity to the mite, which causes the severe itching associated with scabies. Consequently, by the time the disease is first noticed, the mite usually has spread over a large portion of the body.

Treatment is entirely a matter of ridding the patient of the mites and includes:

- 5% permethrin cream is applied to the skin from the neck down at bedtime and washed off the next morning. Dermatologists recommend that the cream be applied to cool, dry skin over the entire body (including the palms of the hands, under finger nails, soles of the feet, and the groin) and left on for 8 to 14 hours. A second treatment one week later may be recommended. Side effect of 5% percent permethrin cream includes mild temporary burning and stinging. Lesions heal within four weeks after the treatment. If a patient continues to have trouble, reinfestation may be a problem requiring further evaluation by the dermatologist.
- 1% lindane lotion is applied from the neck down at night and washed off in the morning. It may be reapplied one week later. Lindane should not be used on infants, small children, pregnant or nursing women, or people with seizures or other neurological diseases, and has been banned in the state of California.
- 10% percent sulfur ointment and crotamiton cream may be used for infants.
- Ivermectin is an oral medicine which may be prescribed for the difficult to treat crusted form. It is not to be used in infants or pregnant women.
- Antihistamines may be prescribed to relieve itching, which can last for weeks, even after the mite is gone.
- Getting rid of the mites is critical in the treatment of scabies. Everyone in the family or group, whether itching or not, should be treated at the same time to stop the spread of scabies. This includes close friends, day care or school classmates, or nursing homes.
- Bedding on clothing must be washed or dry cleaned.

Successful eradication of this infestation requires the following:

- See a dermatologist as soon as possible to begin treatment. Remember, although you may be disturbed at the thought of bugs, scabies is no reflection on your personal cleanliness.
- Treat all exposed individuals whether obviously infested or not. Incubation time is 6-8 weeks so symptoms may not show up for a while. If you do not treat everyone, it is as if you were never treated.
- Apply treatment to all skin from neck to legs — this includes between toes, the crease between the buttocks, etc. If you wash your hands after application, you need to reapply the medication to your hands again.
- Wash clothes. Do all the laundry with the hottest water possible. The mite is attracted to scent. Any clean clothes hanging in the closet or folded in the drawers are OK.
- Items you do not wish to wash may be placed in the dryer on the hot cycle for 30 minutes, or pressed with a warm iron.
- Items may be dry-cleaned.
- Change the bedding.
- Carpets or upholstery should be vacuumed through the heavy traffic areas. Vacuum the entire house and discard the bag, just to be on the safe side.
- Pets do not need to be treated.
- Items may also be placed in a sealed plastic bag and placed in the garage for two weeks. If the mites do not get a meal within one week, they die.

Ticks of varying kinds and sizes may infect the skin and cause severe eruptions. They are picked up frequently in brushy areas or by contact with dogs or other animals that carry them. The female tick attaches itself to the skin by its nose and draws blood for food from the underlying vessels. After several hours, the tick will become filled with blood and drop from the skin. If pulled off by force, the proboscis may be left in the skin and cause an infected sore. The greatest danger from ticks is the possibility that the tick may carry some infectious microorganism and transmit it to the person it feeds upon. Rocky Mountain spotted fever is one such severe infection carried by certain ticks (*Dermacentor andersoni*). See also **Rickettsial Diseases**; and **Tick (Arachnida, Acarina)**.

Chigger bites result from small mites or bed bugs (*Trombicula irritants*). These mites secrete a keratolytic agent that dissolves the outer layer of skin upon which the animal feeds, and causes a red and intensely itching swollen area. The mites are picked up from grasses and brush, and consequently affect the legs and lower portions of the body most often. They accumulate usually underneath garters and belts and in other areas where tight clothing restricts their movement. Chigger bites can be prevented by rubbing wet "sulfur-foam" impregnated material on the extremities before going into chigger-infested areas. See also **Chigger (Arachnida, Acarina)**.

Lice

Pediculosis is caused by infestations of the skin by lice. See also **Pediculosis**.

Bedbugs

These are small, odorous, wingless bugs (*Cimicidae*) that feed on the blood in a manner similar to that of lice. The reaction to bedbug bites varies among different individuals, but generally consists of small, red punctures surrounded by swollen, inflamed areas. The swellings may be painful. The use of soothing ointments to prevent scratching frequently causes the inflammation to subside in a short time. A building that contains bedbugs requires fumigation in order to destroy them completely, because bedbugs live during the daytime in crevices in the floors and walls and in furniture and are difficult to find. Fumigation may be accomplished with hydrocyanic acid gas (a dangerous poison), or fumes of sulfur, formol, or other vapors. Fumigation should be handled by experts. See also Begbug (Insecta, Hemiptera).

Fleas (Insecta, Siphonaptera) live, for the most part, on lower animals, but occasionally infest human beings. They feed on blood, and leave swollen, reddened areas on the skin that may be severe to a sensitive skin. Such diseases as typhus and plague are carried by rat fleas. Infested pets should be treated with various dusting powders and houses can be cleared of fleas by spraying or scrubbing with disinfectants. Sand fleas burrow into the skin in order to deposit their eggs. They live in dry sandy soil in warm climates, and most often affect the feet, ankles, and legs. The reddened swelling which they cause may become the size of a pea or larger and is susceptible to secondary infection by bacteria. Strong soap and soothing ointments generally correct this condition after several days. However, the lesion disappears much more rapidly if a physician removes the flea and its "cocoon" from the skin. See also **Flea (Insecta, Siphonaptera)**.

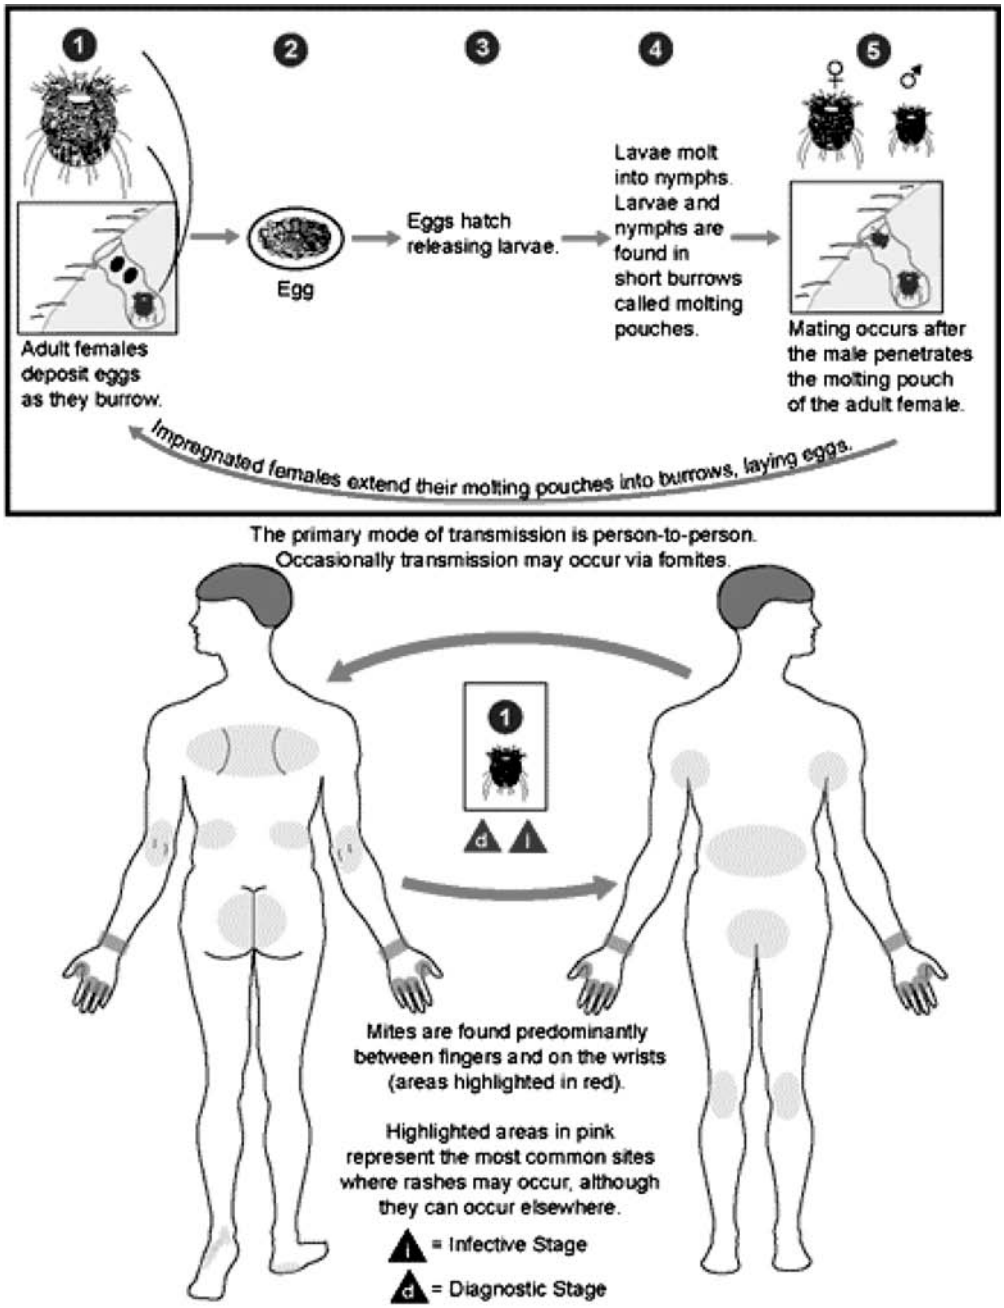

Fig. 1. *Sarcoptes scabei* undergoes four stages in its life cycle; egg, larva, nymph and adult. Females deposit eggs at 2 to 3 day intervals as they burrow through the skin (1). Eggs are oval and 0.1 to 0.15 mm in length (2) and incubation time is 3 to 8 days. After the eggs hatch, the larvae migrate to the skin surface and burrow into the intact stratum corneum to construct almost invisible, short burrows called molting pouches. The larval stage, which emerges from the eggs, has only 3 pairs of legs (3), and this form lasts 2 to 3 days. After larvae molt, the resulting nymphs have 4 pairs of legs (4). This form molts into slightly larger nymphs before molting into adults. Larvae and nymphs may often be found in molting pouches or in hair follicles and look similar to adults, only smaller. Adults are round, sac-like eyeless mites. Females are 0.3 to 0.4 mm long and 0.25 to 0.35 mm wide, and males are slightly more than half that size. Mating occurs after the nomadic male penetrates the molting pouch of the adult female (5). Impregnated females extend their molting pouches into the characteristic serpentine burrows, laying eggs in the process. The impregnated females burrow into the skin and spend the remaining 2 months of their lives in tunnels under the surface of the skin. Males are rarely seen. They make a temporary gallery in the skin before mating.

Transmission occurs by the transfer of ovigerous females during personal contact. Mode of transmission is primarily person to person contact, but transmission may also occur via fomites (e.g., bedding or clothing). Mites are found predominantly between the fingers and on the wrists. The mites hold onto the skin using suckers attached to the two most anterior pairs of legs

Spider and Centipede Bites

These are usually harmless unless they result in secondary infection. Other than immediate pain, they usually produce only an itching, swollen area on the skin surrounded by some degree of reddening. However, a particularly poisonous variety, the black widow spider (*Lactrodectus mactans*) may cause severe systemic symptoms that require immediate medical attention.

Hookworm is a small, parasitic worm (*Ancylostoma duodenale* or *Necator americanus*) which is regarded primarily as an intestinal parasite, although it produces characteristic skin symptoms. The dermatosis is

caused by an invasion of the skin by the young, or larvae, of the worm, and occurs several months before the general systemic symptoms may be pronounced. The earliest signs are in the soles of the feet, since it is through the soles that the worm originally enters the body from the soil. Small, reddened pimples develop into blisters which may eventually become pus-filled. This disease is serious and requires prompt medical attention. In *sandworm disease*, which is generally caused by hookworms carried by cats or dogs, the larvae may cause extensive winding burrows in the skin. The condition is also referred to as *creeping eruption*.

Swimmers' itch is thought to be caused by a small aquatic worm, which invades the skin of persons who swim or wade in contaminated water. Reddened itching pimples or patches develop a day or two after exposure. The disease may be prevented by thoroughly bathing with soap and rubbing the skin with a towel after exposure.

Red ants that occur in the southeastern United States bite when disturbed and leave lesions that may require weeks to heal. See also **Ant (Insecta, Hymenoptera)**.

Molds and Fungi

A large number of skin diseases of varying severity are caused by molds or fungi. Two of the most common of these diseases are ringworm and athlete's foot.

Ringworm (tinea) is caused by the genera *Microsporum*, *Trichophyton*, or *Epidermophyton*, all of the fungus family. The disease usually takes the form of one or several raised, round sores on the skin, which seem to heal in the center while the edges continue to grow outward. Occasionally, the healed centers become reinfected, and a second ring develops and grows within the original ring. In some types of ringworm, there is no healing of the center and the lesion continues to grow. The sores of ringworm begin as small, slightly raised areas with a reddish color. As they enlarge, they become redder, and often contain one or many blistered areas. There may be a slight itching or burning sensation.

A less common type of ringworm appears most frequently in the crotch or under the arms. Called "jock-strap itch." dhobie itch, or *tinea cruris*, it does not heal in the center, and may cover large areas of the skin. This type of ringworm lacks the circular appearance of the common disease, but often resembles butterfly wings when the sore spreads over the inner surface of both legs.

Ringworm of the scalp is common among children, but relatively rare in adults. It produces areas of partial baldness, which are usually temporary. Because children are highly susceptible to this type of ringworm, outbreaks sometimes occur in schools.

Normally, the patient with ringworm is treated with griseofulvin, an antibiotic compound especially effective against certain fungus infections and is derived from a species of *Penicillium mold*. The drug is usually taken orally for several weeks, but in refractory cases must be taken for 4 months or longer. A few types of ringworm do not respond to this drug.

Ringworm is a highly contagious disease. It can be spread by animals as well as by human beings. Dogs and cats that are not bathed frequently are common sources of human infection. Ringworm may be acquired by direct contact with the infection, or it may spread to other areas of the skin of a single individual. Objects handled by infected individuals also carry the fungus. Occasional sources of infection are the backs and arms of theater chairs, combs, and brushes. Fungi thrive on damp, warm skin, especially in areas such as the crotch, where perspiration is unable to evaporate readily. See also **Dermatophytosis**.

Athlete's foot (tinea pedis) is a fungus infection. Among primitive peoples unaccustomed to wearing shoes, it is rare. Contrary to general opinion, athlete's foot does not appear to be easily transmitted from one person to another by the use of common showers or shared facilities. Individual susceptibility and foot hygiene appear to be more important. When the skin remains warm and moist for long periods, fungi of the genus Trichophyton find optimum conditions to invade the dead outer layer (*stratum corneum*) and begin to grow. Two major types of athlete's foot can be distinguished. In the more common forms, called *intertriginous*, a crack or fissure appears in the skin, usually at the base of the fifth toe or between the fourth and fifth toes. In most cases, there is also a visible mass of loose dead skin clinging between the toes. When this loose skin is removed, the skin beneath appears reddened and shiny. In the second type, *squamous-hyperkeratotic*, the disease commences with a reddening and subsequent scaling and thickening of the skin, usually also between the toes. Sometimes areas with increased amounts of the horn-like material of the skin (*keratin*) are observed and these may resemble calluses. Both types of athlete's foot may spread to cover part or all of the soles. Both feet may be involved, but more frequently attacks occur to a greater extent on one foot than on the other. The hands are rarely affected.

Treatment of serious cases of tinea pedis may require the administration of oral micronized griseofulvin for a period of weeks. See also **Dermatophytosis**.

Pityriasis versicolor or chromophytosis is a rather common fungus infection in which there appear fawn-colored patches on the trunk and limbs. It is most common among young adults. The colored patches that occur in chromophytosis actually may be lighter than the surrounding skin in dark-complexioned persons. See also **Pityriasis**.

Actinomycosis is caused by a mold that ordinarily affects the respiratory system. When it infects the skin, it generally involves the mouth, jaw, neck, shoulders, or back. Red swollen areas slowly develop and exude a pus-like material. The involvement of the skin is usually secondary to an infection of the underlying tissues. Actinomycosis is a dangerous condition, but does respond to drugs when it has not become too advanced prior to medical attention. See also **Actinomycosis**.

Systemic Causes

Several skin disorders are manifestations of some deeper causation, such as a malfunction of body chemistry, which may involve various glands, hormones, and other biochemicals within the body.

Acne. This is a very common skin condition, notably in connection with teenage development. Acne vulgaris is a chronic disorder of the pilosebaceous units and generally is confined to the face, chest, and back. Some breakthroughs in treating the disease have occurred during the past few years. See also **Acne Vulgaris**.

Psoriasis. This disease affects up to 2% of the population (U.S.). Adult whites with the disease far exceed the adult black population. The lesions consist of rounded, reddish, dry, scaly patches covered by grayish-white, mica-like scales. These patches may spread and become extensive. The disorder is recurrent, tending to recede during summer in temperate climates. In general, psoriasis is most often seen on the scalp, nails, lower back, knees, and elbows. It will often appear in the same place on both sides of the body. The patches can range in size from smaller than a dime to larger than a hand. Heredity is considered to be a factor, although the genetic mechanisms involved are poorly understood. Secondary causative factors may include infection, local trauma, disturbances in body chemistry, and psychosomatic influences. Frequently in psoriasis there are accompanying alterations in the quality of the nails. Ice-pick pits, so-called, and longitudinal ridging on the nails are characteristic. The relationship of psoriasis to arthritis has been known for 150 years.

Psoriasis occurs in a variety of forms that differ in their intensity, duration, location, shape and pattern of scales. The most common forms are:

- *Plaque psoriasis*, or *psoriasis vulgaris*, is the most common form of psoriasis. It is characterized by raised, inflamed, red lesions covered with a silvery-white buildup of dead skin cells (scales). This is found primarily on the trunk, elbows, knees, scalp and finger or toe nails.
- *Pustular psoriasis* is a rare form characterized by small pustules (whitehead-like lesions) found all over the body or confined to the palms, soles and other isolated areas of the body.
- *Guttate psoriasis* occurs most frequently in children and is characterized by numerous small, red, drop-like scaly macules that develop rapidly over a wide area of skin. This may appear following an infection, most frequently Strep throat.
- *Inverse psoriasis* occurs in the armpit, under the breast, in skin folds, around the groin, in the cleft between the buttocks and around the genitals. It is usually pink and irritated but lacks the thick scale seen in other forms of psoriasis.

Some dermatologists classify psoriasis as mild, moderate, or severe. Mild psoriasis is considered to be scaling over less than 5-10 percent of the body, moderate psoriasis is considered to be scaling over 10 to 20 percent of the body and severe psoriasis is considered to be scaling over 20 percent of the body.

In 5 percent of all psoriasis sufferers, arthritis will develop. This condition is called psoriatic arthritis. Arthritis is inflammation of a joint, usually accompanied by pain, swelling and changes in joint structure. See also **Arthritis (Infectious)**.

After years of research, the cause of psoriasis remains of unknown origin, however, heredity seems to play a role in susceptibility (1 in 3 people with psoriasis have an immediate relative with the disease).

Psoriasis can be triggered by a number of factors, such as stress, climate changes, streptococcal or HIV infection, superficial wounds, physical illness, or taking certain drugs such as lithium, beta-blockers such as propranolol, quinidine (a heart medication) or antimalarial medications.

Dermatologists diagnose psoriasis by examining the skin and noting specific characteristics of the lesions. Occasionally they may need to biopsy the lesion and examine the skin under a microscope to confirm diagnosis. There are no blood tests or other laboratory tests available for establishing diagnosis.

There is no cure for psoriasis at this time, but there are various treatments that can, in most cases, temporarily clear the skin of psoriasis. Occasionally, psoriasis will go into spontaneous remission without treatment. For most patients, however, one or more of the following treatments is usually necessary:

Topical Therapy (usually used to treat mild to moderate psoriasis):

- Emollients (moisturizers) help soften scales and reduce discomfort
- Steroid creams and ointments help reduce inflammation. They range in strength from very potent to mild. (See below)
- Tazarotene (Tazorac) is a topical retinoid for treating mild to moderate plaque psoriasis
- Anthralin or other coal tar preparations help to slow skin cell reproduction
- Vitamin D3 or calcipotriene (brand name Dovonex)
- Bath solutions, such as mineral salts or oatmeal additives, assist in soothing skin and encouraging healing

Phototherapy (used alone or in combination with other therapies to treat moderate to severe psoriasis):

- Ultraviolet Light B (UVB), either outdoors or from a light box in a physician's office, helps to heal lesions.
- Psoralen and Ultraviolet Light A (PUVA) - involves the combined use of a photosensitizing medication, called psoralen and a long-wave ultraviolet light (UVA).
- Excimer lasers may be used to treat a small, localized area of psoriasis. They are a way to deliver UVB light directly to the psoriasis without exposing normal skin.

Internal Medications (used for moderate to severe psoriasis):

- Biologic drugs are taken from living material (human, plant, animal, or microorganism). They act on parts of the body's immune system to prevent inflammatory disorders, including psoriasis. Unlike drugs that suppress the entire immune system, biologics can fight more selectively and target only those chemicals involved in causing psoriasis. Only recently have biologics targeted toward psoriasis begun to emerge as potentially promising new treatment options. Etanercept (Enbrel) and infliximab (Remicade) belong to the class of biologic medicines called tumor necrosis factor (TNF) blockers. These work by blocking the activity of TNF, the primary cytokine involved in psoriasis. Alefacept (Amevive) and efalizumab (Raptiva) are T-cell blockers and block the overactive T-cells. Unfortunately, each of these drugs requires frequent injections with needles. These medications are also relatively new and extremely expensive.
- Methotrexate (MTX) helps to slow down cell reproduction and decrease inflammation.
- Retinoid Therapy, including acitretin (Soriatane), helps to reduce inflammation.
- Cyclosporin A slows the immune system overall and may help decrease the inflammation of psoriasis.

Rosacea. Commonly, but mistakenly referred to as "adult acne," rosacea causes redness and inflammation of the facial skin, and sometimes on the neck and upper chest. About 50 percent of the time it involves the eye area as well. It tends to occur more frequently in people with fair skin, and may be an inherited trait. Some people can have more than one type of rosacea at a time; others never develop more than one type. No single factor adequately explains the pathogenesis of this disorder. A combination of environmental factors and genetic predisposition may cause it to develop. Some links have been established to a mite that lives in facial hair follicles, and possibly others to Helicobacter pylori, a bacterium (residing beneath the mucus layer next to the stomach) that has been associated with the occurrence of gastritis and peptic ulcers. Some researchers believe that something causes blood vessels to swell, creating flushing and redness.

The condition may commence with a prominent translucent flush of the cheeks, nose, chin and at times, the entire face, may have a rosy hue. The nose may enlarge. As the disorder progresses, inflammatory red bumps (papules) are present as well as pus-filled bumps (pustules). There is a vascular component with telangiectasias (a lesion formed by a dilated capillary) and a tendency to flush easily with burning or stinging. Unlike acne, there are few or no blackheads or whiteheads (comedones).

When the eyes are affected (in about 50 percent of the cases), symptoms include burning and tearing or the feeling that there is a piece of grit in the eye. The eyelids may swell due to infection. Usually this condition does not impair vision.

Spontaneous remissions of rosacea are rare. Usually, without treatment, the condition will gradually worsen.

Persons most susceptible to rosacea are middle-aged and older people (usually between 30 and 60), which affects approximately 13 million people in the United States. Some occurrences of the disease may be related to menopause, although this has not been firmly proved. Also, some researchers suspect an emotional linkage to rosacea. Repressing anger, fear, or other strong emotions tends to increase the redness that is symptomatic of the condition. Certain drugs may dilate the blood vessels in the skin and worsen rosacea. These drugs include theophylline and nitroglycerin.

Overindulgence of alcohol, spicy foods, hot drinks, and smoking are believed to complicate rosacea by causing blood to rush to the affected areas and aggravate flushing. The patient with rosacea should limit exposure to sunlight, avoid extreme hot and cold temperatures, undue rubbing or massaging of the face, and irritating cosmetics and hair sprays.

Rhinophyma, an exaggerated form of rosacea (typified by the nose of the famous comedian W.C. Fields) can occur in persons who do not consume any alcohol. Rhinophyma can be treated with surgery. Excess tissue that has developed can be carefully removed with a scalpel, laser, or through electrosurgery. Dermabrasion can help improve the appearance of scar tissue on facial skin, but, in some cases, regrowth may occur.

The goal of treatment is to improve appearance and keep the condition under control. It's a good idea to keep a record of what factors seem to trigger the flare-ups as this may help your doctor determine the best course of treatment.

Some dermatologists may prescribe topical antibiotics such as metronidazole (gel or cream) or clindamycin (solution, gel or lotion). Five to eight weeks of treatment may be needed for a significant response.

Oral antibiotics may be tried if topical treatment fails. Commonly used ones used include tetracycline, minocycline, erythromycin, and doxycycline.

Isotretinoin is sometimes used for severe rosacea, but it is linked to a number of adverse side effects. In particular, women of childbearing age should not be or get pregnant while taking Isotretinoin as this medication can cause birth defects.

Electrosurgery and laser surgery can sometimes be used to treat redness and rhinophyma (enlargement of the nose). A satisfactory treatment for the skin lesions is a yellow light laser.

Avoiding the use of facial products that irritate your skin, along with consistent use of sunscreen with an SPF of 15 or higher is recommended for people with rosacea. It may help to minimize your stress level as well.

Seborrheic Dermatitis. This is a chronic disorder in which inflammation occurs in those areas having the greatest numbers of sebaceous glands (oil glands) of the skin, including the scalp, sides of the nose, eyebrows, eyelids, skin behind the ears, and middle of the chest. However, other areas, such as the navel and skin folds under the arms, breasts, groin, and buttocks, may also be involved, though less frequently. The affected skin is red and is covered by yellowish, greasy-appearing scale. Mild itching may be present.

The condition is seen most often in infants (2 to 12 weeks old), in middle age, and in the elderly. The condition in infants usually clears without treatment by age 8 to 12 months. Among adults, there is increased incidence in Parkinson's disease patients. It may also accompany the recovery of stressful medical situations, such as a heart attack. Thus far, seborrheic dermatitis has not been noted to precede a cancerous skin condition. It is still controversial whether diet and food allergies have any role in the development of the disorder. Vitamin dosage appears to have no function in the disorder.

Seborrheic dermatitis is distinguished from seborrhea (dandruff). See also **Seborrhea**.

Autoimmune Skin Diseases. There are over 50 vesiculobullous diseases, which are characterized by local or general distribution of blisters. Among these are *pemphigus vulgaris, bullous pemphigoid, dermatitis herpetiformis, erythema multiforme, keratosis follicularis* (Darier's disease), and *epidermolysis bullosa*. One of the most intensely studied of these diseases is pemphigus vulgaris. The Todd reference listed describes an extensive study made of Class II major histocompatibility (MHC) molecules which have an immunoregulatory role. See also **Pemphigus Vulgaris**.

Chemical Irritants

Strong chemical substances, such as acids, alkalis, and salts or a vast variety of organic compounds, can injure or literally remove tissue (burn), which after proper treatment will be healed, often with scarring. More insidious are those substances that enter the body through contact, inhalation, or drinking and eating, causing permanent damage or persistent responses in the form of allergies. An example is the rash caused by penicillin and other drugs that may be consumed by certain individuals. The skin frequently is an excellent indicator of body intolerance. Such situations generally fall within the realm of allergy and diet. Check alphabetical index. Because of the many thousands of substances the average individual may be exposed to, the identification of specific irritants frequently is difficult and time consuming. See also **Allergy**. Hives are described under Urticaria.

Radiation

Various forms of radiation, including ionizing radiation, adversely affect human function in one way or another. The most common, but also extremely seriously damaging, radiation is that of the ultraviolet radiation component of sunlight. Here the primary target for damage is the skin, often leading to life-threatening cancers. See also **Skin Cancer**.

Exposure to Cold

Chillblain and frostbite are two common dermatoses that occur as the result of overexposure to cold. See also **Chilblain**.

DERMATOPHYTOSIS. Dermatophytosis (tinea or ringworm) of the scalp, glabrous skin, and nails is caused by a closely related group of fungi known as dermatophytes which have the ability to utilise keratin as a nutrient source, i.e. they have a unique enzymatic capacity (keratinase). See also **Dermatitis and Dermatosis**.

The disease process in dermatophytosis is unique for two reasons: Firstly, no living tissue is invaded the keratinised stratum corneum is simply colonised. However, the presence of the fungus and its metabolic products usually induces an allergic and inflammatory eczematous response in the host.

Dermatophytosis (tinea) may affect the scalp (tinea capitis), the bearded skin of the face (tinea barbae), the body (tinea corporis - mainly affecting children), the groin (tinea cruris or jock itch), the nails (tinea unguium), and the feet (tinea pedis or athlete's foot). These disorders vary from mild inflammations to acute vesicular reactions.

Although remissions and exacerbations are common, with effective treatment, the cure rate is very high. However, about 20 percent of all infected people develop chronic conditions.

Tinea lesions vary in appearance and duration.

- Tinea capitis may appear as small, spreading papules (bumps) on the scalp that may progress to inflamed, pus-filled lesions. Patchy hair loss with scaling may occur.
- Tinea barbae appears as folliculitis in the bearded area. See also **Folliculitis**.
- Tinea corporis might include flat skin lesions at any site except the scalp, bearded skin or feet. These lesions may be dry and scaly or moist and crusty. As they enlarge, their centers heal, producing the classic ring-shaped appearance.
- Tinea cruris will include raised, sharply defined and itchy red lesions in the groin area that may extend to the buttocks, inner thighs and external genitalia.

- Tinea unguium starts at the tip of one or more nails. Fingernail infection is much less common. Inspection will reveal gradual thickening, discoloration and crumbling of the nail. Eventually, the nail may be completely destroyed.
- Tinea pedis may present with extreme itching and pain, especially while walking, because of the scaling and blisters between the toes.
- Tinea versicolor (pityriasis versicolor) is a mild, superficial infection of the skin (usually of the trunk). Lesions are asymptomatic and usually tan, pink, white or brown macules (flat patches). See also **Pityriasis**.

Causes, Diagnosis and Risk Factors

Tinea infections result from several different fungi. Transmission can occur directly through contact with infected lesions or indirectly through contact with contaminated articles such as shoes, towels or shower stalls. Another predisposing factor is the combination of warm weather and tight clothing, which encourages fungus growth.

Some of the fungi involved in these conditions primarily infect animals, but they may also be transmitted from animals to humans. Cats may have an infection, but may not be suspected until lesions appear on their owners.

Diagnosis must rule out other possible causes of the signs and symptoms, which may include eczema, psoriasis, and contact dermatitis.

A microscopic examination of some lesion scrapings usually confirm tinea infection. This is called a KOH (potassium hydroxide) preparation. Culture of the affected area, which may take weeks, may help identify the infecting organism.

Prevention and Treatment

The skin should be kept dry, since moist skin favors the growth of fungi. Dry the skin carefully after bathing and let it dry before dressing. Loose-fitting underwear is recommended. Socks should be changed daily. Sandals or open-toed shoes may be beneficial. Talc or other drying powders may also be helpful.

Topical antifungal preparations should be effective in treating small, uncomplicated tinea infections located in areas other than the scalp. These include topical clotrimazole and miconazole (available over the counter) and terbinafine cream.

Sometimes, oral antifungal medication may be required if the condition is severe. Medications may include griseofulvin, itraconazole, terbinafine and fluconazole. See also **Antiparasitic Agents, Antimycotics**.

Tinea capitis (scalp), regardless of severity, is usually treated with oral antifungal medication, since topical antifungals do not penetrate hair follicles well. Corticosteroids may sometimes be used for the treatment of severely inflamed or potentially scarring lesions, such as scalp infections. Fungal infections involving the nails (onychomycosis) require oral treatment as well, because the dermatophyte is found deep in the nail. See also **Onychomycosis (OM)**.

Tinea versicolor may be treated with selenium sulfide lotion or ketoconazole shampoo.

Occasionally, the question arises as to whether a concurrent bacterial infection is complicating a fungal infection. This situation most commonly occurs when highly inflamed scalp lesions are draining purulent (pus) material. The lesions usually resolve with systemic (oral) antifungal and systemic corticosteroid therapy. See also **Bacterial Diseases**.

DERMESTID *(Insecta, Coleoptera)*. Any of the small beetles of the family *Dermestidae*, including the buffalo carpet moth. They damage clothing, woolen articles, and museum specimens.

DERMOLITH. A term proposed by T.A. Jaggar in 1917 for ropy, wrinkled or pahoehoe type of basic lava, such as occurs in the volcanic islands of Hawaii.

DERMOPTERA *(Mammalia)*. This order of the *Mammalia* is represented by only one genus, variously called flying lemur, colug, kobugo, kaguan, or kobego. The classification of this gliding mammal has created problems for many years. At one time it was assigned to the bats; at another time to the Insectivores; and at still another to the Primates, by way of the lemurs. Kobegos or flying lemurs are about 18 inches (46 centimeters) in length and have folds of skin along their sides, the front paws and hind feet are fully webbed. Thus, upon leaping, the animals spread their limbs and become furry kites, which permit gliding travel for considerable distances. Glides may measure up to 100 feet (30 meters), with only 1 foot (0.3 meter) dropped for every 5 feet (1.5 meters) of essentially horizontal travel. These animals possess several interesting physiological and anatomical qualities, likening them in various ways to other orders of mammals as previously mentioned. One type of kobego is found in Indonesia, Malaysia, and Thailand, while a second type occurs in some of the Philippine islands. They diet on leaves, flowers, and fruits. The animals sleep by hanging upside down from a tree branch. Despite their airborne capabilities, the kobegos are unlike bats in most other respects.

DESALINATION. As generally used, the term describes the production of water appropriate for human consumption from seawater and brackish water. Seawater averages about 35,000 ppm of total dissolved solids (TDS). Brackish waters TDS range from 2000 ppm upwards. The maximum TDS of water considered tolerable and acceptable for continued human consumption is about 500 ppm, although water containing up to 1000 ppm TDS may be consumed for short periods.

Desalination processing techniques fall into three groups:

1. *Processes based on a change of phase* — distillation and freezing.
2. *Processes based on selective transport using membranes* — electrodialysis and reverse osmosis.
3. *Processes based on chemical bonding* — ion exchange.

Distillation and freezing process have advantages for high-salinity water, such as seawater, because the energy required is independent of salt content. Electrodialysis and ion exchange are best suited for brackish waters. Reverse osmosis is competitive for desalting both seawater and brackish water. A general desalting plant schematic of the components common to all desalting systems is shown in Fig. 1. The raw saline water is treated to prepare the water for desalination and to ensure more efficient and trouble-free performance of desalination systems. The pretreated saline water enters the desalting plant, where the product water stream is the desalting plant's primary output; a brine stream is also produced. The product water is mixed with suitable chemicals in the post-treatment step, depending upon the intended use of the water. The treated product water is then transferred to a distribution system.

Distillation

In distillation, impurities from saline water or brine are removed by boiling the saline water, collecting the water vapor and then cooling the vapor until it condenses. The basic equipment used is an evaporator. Commercial evaporators operate under vacuum to utilize the maximum available temperature range for heat transfer. The three major classifications of distillation systems currently in use are: (1) multistage flash distillation (MSF); tube evaporation (VTE, HTE); and vapor compression (VC).

Multistage flash distillation is used widely by itself and also in conjunction with steam power plants to produce potable water from seawater. The MSF process is illustrated in Fig. 2. Multistage flash distillation incorporates flashing of heated brine as it enters a stage in which the vapor pressure is maintained so that the boiling point of

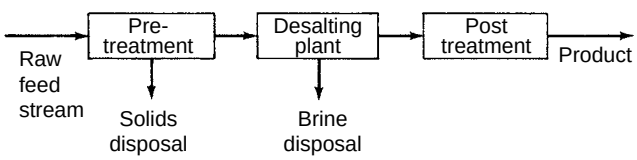

Fig. 1. Generalized schematic of a desalting plant.

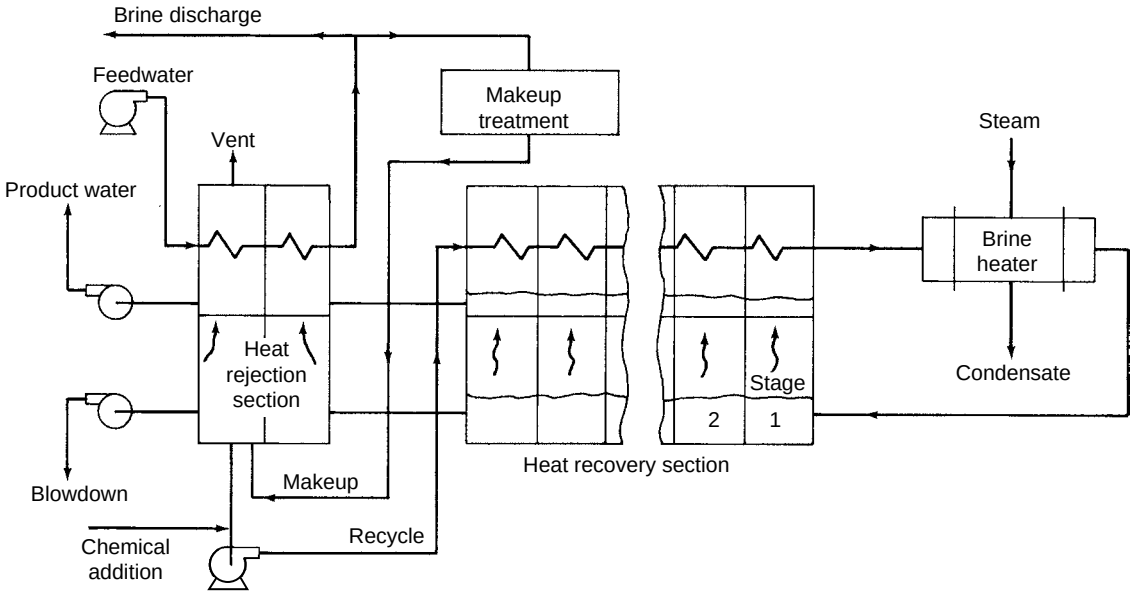

Fig. 2. Multistage flash evaporation process used in desalination.

the brine is below its incoming temperature. Flashing occurs in steps as the heated brine passes in series through a number of stages at successively lower pressures. The multistage distillation process is the most economic of the high-temperature processes in terms of energy and cooling water requirements. The optimum number of stages is determined by an economic and technical evaluation. Modern MSF designs typically have three or four heat rejection stages, plus twenty flash stages.

Tube evaporators may be designed as vertical tube evaporators (VTE) or horizontal tube evaporators (HTE). In the VTE, vapor produced in one effect is condensed in the next effect. The effect is an evaporator chamber receiving heat from an external source or from a higher effect and producing vapor and brine which may serve as a heat source for the next effect. To obtain high efficiency in the use of heat energy, the process is repeated in several evaporator effects arranged in series. See also **Evaporation**.

Vapor compression uses the reverse principle of multieffect distillation. As a vapor is compressed, its temperature and pressure increase. The compressed vapor can be used instead of fresh steam as a heat source at the high-temperature end of the distillation process.

All distillation processes are based on energy-consuming phase changes to convert seawater to potable water. Careful consideration of pretreatment requirement and materials of construction is necessary to provide a satisfactory system.

Electrodialysis

Electrodialysis (ED) is a membrane process based on the ability of semipermeable membranes to pass select ions in feedwater. A direct current electrical field transports the ions through the membranes. In the basic system, alternating cation- and anion-selective membranes are placed in an electrical field. An electrodialysis stack schematic is shown in Fig. 3. The cation-selective membranes permit only the transport of cations; anion-selective membranes allow only the transport of anions.

The transport of ions across the membranes results in ion depletion in some cells and ion concentration in alternate ones. Water exiting from the ion-depleted cells is the desalted product; water leaving the ion-concentrated cells is the brine. The cell pair consists of a cation-selective membrane, an ion-depleted cell, an anion-selective membrane, and an ion-concentrated cell. A commercial electrodialysis unit consists of hundreds of cell pairs stacked vertically and clamped between two huge oppositely charged electrodes. Electric energy is consumed in proportion to the quantity of salts to be removed. Economics usually limit the application of ED to feedwaters of less than 10,000 ppm total dissolved solids (TDS). The electrodialysis process does not remove organics, colloidal matter, or bacteria. See also **Membrane Separations Technology**.

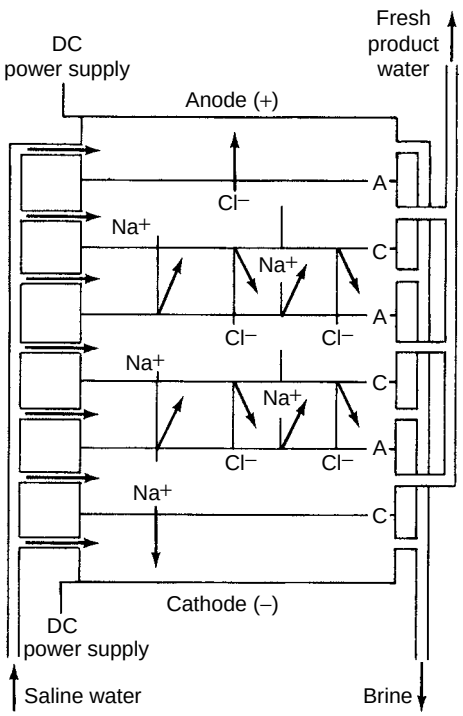

Fig. 3. Schematic of electrodialysis stack used in desalination and other separation processes.

Reverse Osmosis

If a solution is placed on one side of a semipermeable membrane and water is placed on the other side, then there is a natural tendency (*osmosis*) for water to diffuse through the membrane to the solute side until an equilibrium osmotic pressure is reached.

If a pressure is applied to the solute side, substantially greater than the osmotic pressure, the water diffuses from the solution through the membrane to the fresh-water side. This phenomenon is called reverse osmosis (RO). In applying this principle to desalination, hydraulic pressure is used to force pure water from saline water through a semipermeable membrane. See Fig. 4. RO membranes may be spiral wound sheets, hollow fine fibers, or tubes. In the spiral wound design, two membranes sheets are glued back to back to form an envelope. When water, under pressure, is passed over the surface of the sheet, pure water passes through the membrane, while the salts are held back on the outer surface of the

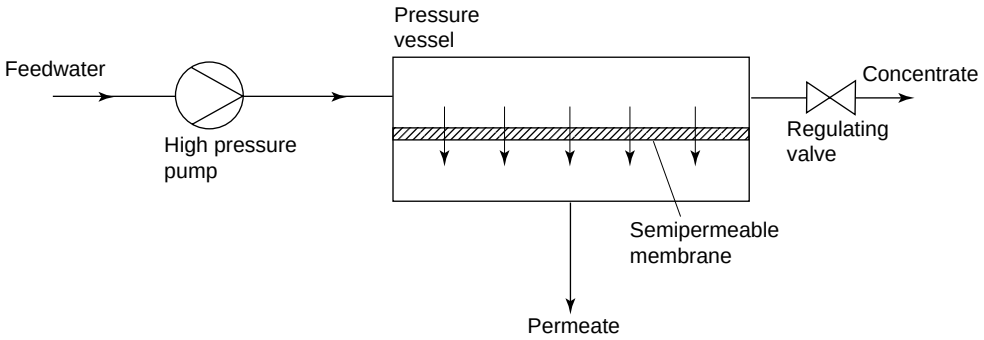

Fig. 4. Schematic of reverse osmosis process used in desalination process. (*Toyobo Co., Ltd., Osaka, Japan.*)

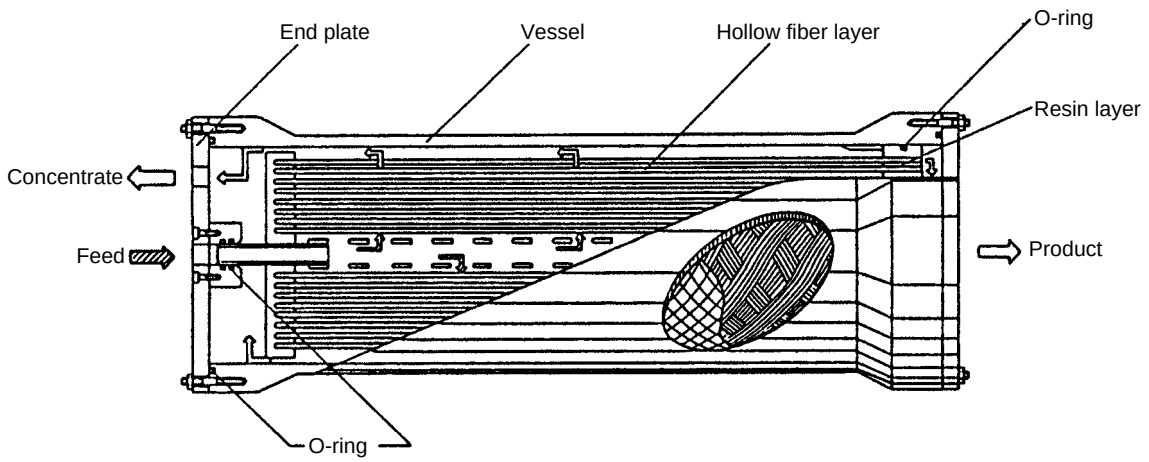

Fig. 5. Hollow fiber reverse osmosis module used in desalination and other separation processes. (*Toyobo Co., Ltd., Osaka, Japan.*)

envelope. The membrane envelopes are separated by mesh spacers and rolled into the spiral configuration. The hollow fiber membrane design places a large number of hairlike hollow elements in a pressure vessel. The membranes have an outside diameter of about 100 to 300 micrometers and an inside diameter of about half that dimension. Normally, the fibers are looped in a U-shape so that both ends are embedded in a plastic tube-sheet. Under pressure, desalted water passes through the fiber walls and flows down the inside of the fibers for collection. The hollow fine fiber design is shown in Fig. 5.

Reverse osmosis performs a separation without a phase change. Thus, the energy requirements are low. Typical energy consumption is 6 to 7 kWh/m^2 of product water in seawater desalination. Reverse osmosis, of course, is not only used in desalination, but also for producing high-pressure boiler feedwater, bacteria-free water, and ultrapure water for rinsing electronic components—because of its properties for rejecting colloidal matter, particle and bacteria.

Ion Exchange

Ion exchange processes use natural or synthetic granular materials that exchange one ion for another. The new (captured) ion is held for a finite period and then released to a regenerating solution. Because regeneration costs increased proportionally with the TDS reduction, the ion exchange process has not been competitive with membrane processes for desalting feedwaters above 1000 ppm TDS. Ion exchange technology is used worldwide in systems ranging from domestic water softeners to large municipal and industrial demineralizers. See also **Ion-Exchange Resins**.

Other Processes

A number of other desalination processes, such as freezing, membrane distillation, and solar humidification, have been used to desalt saline waters. Based on their commercial success, these processes can be considered as minor desalination processes.

In the *freezing process*, dissolved salts are naturally excluded during the formation of ice crystals. When seawater is frozen, fresh-water ice crystals are formed and the salt is concentrated in the remaining brine solution. The ice crystals can be separated from the brine, washed, and melted, to yield fresh water.

In the *membrane distillation process*, combined use of distillation and membranes is made. Salt water is warmed to produce vapor. This vapor passes through porous membranes, which are permeable to vapor but not to the liquid phase. The vapor is condensed on a cooled surface to produce fresh water. The main advantage of this process is its simplicity and the need for only small temperature differentials to operate.

The solar humidification process is represented schematically in Fig. 6. This process generally imitates a part of the natural hydrologic cycle in that the saline water is heated by the sun's rays to enhance vapor production. The vapor is then condensed on a cool surface and the condensate collected as product water.

Worldwide Installations

As of 1990, the worldwide inventory of total capacity of installed desalination plants was approximately 13.2 million cubic meters (nearly 3.5 billion U.S. gallons) per day.

Two representative installations are shown in Figures 7 and 8.

DESARGUES, GIRARD (1591–1661). Desargues was a French engineer who invented a non-Greek way of doing geometry, which we now call "modern" geometry. His new ideas probably arose from his work on perspective. Desargues also wrote about practical building subjects, such as cutting of stones for use in building.

See also **Geometry**.

J. M. I.

DESCARTES, RENE (1596–1650). Descartes was a French mathematician and physicist. He had a Jesuit school education and spent much of his early years studying, traveling, and writing books. In his lifetime he had the honor of teaching philosophy to Queen Christina of Sweden.

Descartes is best remembered for employing the method of deduction to discover mathematical and scientific truths. He is credited with the development of analytical geometry.

See also **Folium of Decartes**; and **Geometry**.

J. M. I.

DESCENDING NODE. That point at which a planet, planetoid, or comet crosses to the south side of the ecliptic; that point at which a satellite crosses to the south side of the equatorial plane of its primary. Also called southbound *node*. The opposite is ascending node or northbound node.

DESCRIBING FUNCTION. The output response of a nonlinear system to a sine wave input will not necessarily be a sine wave. The actual output will depend on the nonlinearity, but will normally have a fundamental mode of the same frequency as the input. The transfer function based on the magnitude ratio and phase angle of the output fundamental versus the input sine wave is defined as the describing function. Application of the describing function allows linear analysis of nonlinear systems.

DESCRIPTIVE GEOMETRY. The theory of graphic representation, invented and developed by Gaspard Monge, 1795. Descriptive geometry deals with the exact representation of objects composed of geometrical forms and of the graphical solution of problems involving the space relationship of these forms.

In modern computer technology, the principles of descriptive geometry are incorporated in computer graphics software.

DESERT (Hydrology). See **Hydrology**.

DESERTIFICATION. Desertification is a degradation of the top layer of the soil that reduces its ability to support plant life and to produce food. As a result, the soil becomes dusty and dry, and it is easily carried away by erosion, which affects wild and domestic animals, wild plants and crops and, finally, humans. Desertification can be the result of human activities or of natural climate changes. In the latter case, the process is very slow and can take several thousand years to produce its effects. A common misconception about desertification is that it spreads from a desert core. The truth is that land degradation can occur where land abuse has become excessive. If it is not stopped in time, desertification spreads from that spot. Eventually, many of these spots merge and form a large homogeneous area. Another misconception is that desertification is the result of droughts. In fact, well-managed land can recover from even a long period of drought with very little adverse effect as soon as rains return. But it is true that droughts can increase the pace of desertification already taking place.

Desertification is a term that has been in use since at least 1949, when Aubreville, a perceptive and well-informed botanist and ecologist, published a book on *Climate, Forets, et Desertification de l'Afrique Tropicale*. Aubreville observed desertification in tropical Africa and understood immediately that the culprit was not the Sahara desert gaining land. He noticed instead that the main reasons behind desertification were tree cutting, indiscriminate use of fire to clear the land, and cultivation.

Many processes can lead to desertification. Logging, for instance, makes the soil unstable on mountain slopes. Eventually, all the soil runs down as a dangerous landslide or mud river and leaves behind exposed rocks, unable to support any life. What is left behind are barren mountains, particularly evident in China. In Europe, one of the leading causes of desertification is overgrazing. In the past, wild animals used to move following the rainfall, always grazing the richest areas. In modern times, the use of fences prevented these movements, and the result was heavy overgrazing that left the soil exposed to erosion. In many areas, desertification is the result of agriculture. A typical example of this is salinization of soil that happens normally when the soil is overirrigated. The water that is not used by plants evaporates, leaving behind salts that concentrate in the soil. Eventually, the concentration of salts in the soil becomes so high that plants cannot survive, again exposing the land to erosion. In same cases, desertification is the more direct result of urbanization, mining, and recreational activities. In any case, the adverse effects are still the same.

As stated at the beginning, desertification is sometimes a slow natural process. As an example, it should be enough to say that 20,000 years ago, the Sahara Desert was a lush forest. This is proved by the fossils of the animals that used to live in this forest. Moreover, pictures taken using radar from the Space Shuttle allow us to identify numerous dry riverbeds under a few meters of sand. This is already happening again due to the global warming on the earth. Many deserts are expanding, even though it is not possible to find a human reason for that. Desertification seems to threaten, in particular, all countries in the Mediterranean region. The coasts of North Africa are already disappearing into the sand, but the same might start happening in Europe. The heat wave of 2003 caused lots of problems. In Italy, many crops were heavily affected, and in the whole Mediterranean region, but in particular in Spain and Portugal, large areas of forest were destroyed by fires.

DESIGN OF EXPERIMENTS. The science of designing experiments so as to obtain unambiguous results of the highest possible accuracy. Four principles of experimental design may be distinguished.

1. *Replication*. Any treatment must normally be applied to more than one experimental unit. This provides greater accuracy than can be obtained from a single observation, since the experimental errors tend to cancel each other; it also provides a measure of the experimental error derived from the variability between replicates.

2. *Randomization*. The decision as to which experimental unit shall receive which treatment should include a random element. This is designed to ensure that every treatment shall have its fair share of the particularly favorable and the particularly unfavorable experimental units.

3. *Local Control*. Any structure in the properties of the experimental units should be utilized fully. Thus if the units fall into relatively homogeneous groups (neighboring plots in a field, animals from the same litter, etc.) comparisons between treatments should be made as far as possible between units in the same group.

4. *Balance*. If the effect of several different factors is to be tested simultaneously, the experiment should, if possible, be laid out in such a way that the contributions of the factors can be separately distinguished and estimated.

SIR MAURICE KENDALL, International Statistical Institute, London

DESORPTION. The reverse of absorption or adsorption, as in the release of one substance which has been "taken into" another by a physical process, or the release of a substance which has been held in concentrated form upon a surface.

DESULFURIZATION (STEEL). See **Calcium**.

DETECTION (Radio). The process of separating the intelligence from the carrier upon which it was modulated for transmission. See also **Modulation**. For the detection of amplitude modulated signals some sort of rectification must be used, since the rapid alternations back and forth of the radio-frequency signal are too fast for the loudspeaker to follow, and even if it did follow them the ear could not respond. Among the earliest radio detectors were various crystals such as galena, silicon, and silicon carbide. These materials, when properly mounted, pass current in one direction and not in the other, so by impressing the modulated signal on them they may be made to serve as detectors. The resulting current is a pulsating D.C., which varies in magnitude with the amplitude of the modulation on the original carrier. Crystals can be used for ultrahigh frequency detection. For home radio and television reception, the most common detectors are semiconductor diodes. Figure 1 shows a typical diode detector circuit.

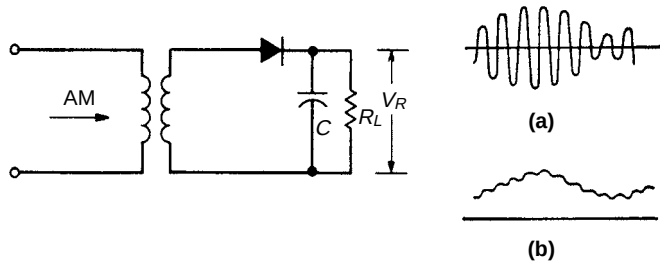

Fig. 1. Semiconductor diode detector circuit with filter and load.

The modulated signal is impressed through the coupling transformer from a preceding amplifying circuit. Current flows through the diode and rectifies the signal (see also **Rectifiers**). This current charges up the capacitor *C*, which, in turn, discharges through the resistor when the diode is not passing current. The capacitor does not completely discharge, but has a voltage across it similar to that shown in (a), while (b) shows the impressed modulated carrier. It is seen that the voltage across the capacitor follows the modulation closely, and by adding additional capacitance-resistance units, even the slight ripples shown on it may be removed. This voltage may be coupled to the input of a transistor amplifier stage and further amplified before being impressed on the speaker.

In the reception of continuous wave radio signals, a heterodyne detector is often used. For such signals to be audible they must be beat (see also Heterodyne) with another signal to produce an audible frequency, since they have no modulation, and hence, even if detected by the usual means, cannot produce a varying output signal. When the continuous-wave radio signal is mixed in an electronic circuit with a locally generated signal that differs in frequency by some audio amount from it, the resultant output of the device contains various component frequencies. Among these is one equal to the difference between the two frequencies mixed in the input. By proper adjustment of the frequency of the local signal this difference can be made any value desired. A common choice is from 500 to 1000 cycles. This gives a pleasing tone for the output. Such reception is called *heterodyne detection*, a somewhat similar process where the difference is used in the first detector of the superheterodyne receiver where the difference is made fairly high (this is the intermediate frequency and is always well above the audible range). When the heterodyning signal is generated by the detector serving as an oscillator at the same time, it is often called *autodyne detection*. (For frequency modulation detection, see **Discriminator**.)

DETECTOR. Any device which indicates the presence of an entity of interest, such as radiant energy, without necessarily yielding quantitative information. The term is essentially similar to *sensor* and *primary element*, namely that part of a measurement system which is exposed to and affected by the variable being measured — as the thermocouple in a temperature-measurement system, or a strain-gage load cell in a force-measurement system. In electronic circuitry, detector denotes that stage of a receiver in which demodulation occurs. In the case of a superheterodyne receiver, this is termed second detector; sometimes termed demodulator.

DETERGENTS. For purposes of this article, detergents are defined as complete washing or cleansing products, which contain among their ingredients an organic surface-active compound (*surfactant*) that has soil-removal properties. Frequently, the term *detergent* is used synonymously with *surfactant*, but common industry practice treats the surfactant as one component of a total detergent product, as is done here. Additionally, this article treats primarily only the so-called synthetic detergents, excluding those products in which soap is the sole or predominant surfactant. Soaps, the alkali salts of long-chain fatty acids, differ significantly in certain important performance properties from the synthetic surfactants and are described separately in this encyclopedia. See also **Soaps**.

The synthetic detergent industry is one of the largest chemical process industries. In 1984, annual U.S. production of synthetic detergents was about 7 million tons, with approximate manufacturer's value of $9 billion. The industry differs from many other chemical process industries, however, in that the bulk of its production is sold directly to individuals for household consumption, primarily as branded products, rather than to industrial or institutional users.

Detergent Ingredients and Their Functions

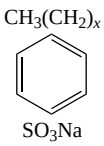
Detergent formulas vary greatly, depending upon the intended end-use application. Differentiation by surfactant type as well as selection of auxiliary ingredients is involved. Some of the ingredients most commonly used in detergent formulas and their functions are as follows.

Surfactants. By definition every detergent product contains one or more types of surfactants. Basically, every surfactant is an organic compound consisting of two parts: (1) a *hydrophobic* portion, normally including a long hydrocarbon chain, and (2) a *hydrophilic* portion, which renders the entire compound sufficiently soluble or dispersible in water or other polar solvent to serve its intended use. Together, these combined hydrophobic and hydrophilic moieties render the compound surface-active — able to concentrate at the interface between a surfactant solution and another phase, such as air, soil, and textile substrate to be cleaned.

Surfactants provide the detergent with the ability to penetrate and wet soiled surfaces, to displace, solubilize, or emulsify various soils, particularly oils and greases, and to disperse or suspend certain soils in solution to prevent their redeposition. In addition, the surfactants provide (to various degrees) whatever foaming or sudsing properties the detergent solution possesses, properties which are necessary for satisfactory use in certain industrial applications and highly desirable to many consumers in household laundry, hand-dishwashing, and personal care uses.

Surfactants in broad use may be classified into three general types: (1) *anionics*, in which the hydrophilic portion of the molecule carries a negative charge; (2) *cationics*, in which the charge of this portion is positive; and (3) nonionics, which do not dissociate but commonly derive their hydrophilic portion from polyhydroxy or polyethoxy structures. *Ampholytic* and *zwitterionic* surfactants are also known and are starting to be of commercial importance.

Of the three main types of surfactants, the anionics are by far the most commercially important class, constituting, in particular, the major surfactant type represented in laundry and hand-dishwashing detergents. Among the anionics, linear sodium alkyl benzene sulfonate (LAS), linear alkyl sulfates, and linear alkyl ethoxy sulfates are by far the most widely used compounds. (The industry converted voluntarily to linear alkyl chains in the mid-1960s to obtain improved biodegradability relative to the branched-chain alkylates formerly used.)



(x ranges fro 9 to 15)

Linear alkyl benzene sulfonate (LAS)

$CH_3(CH_2)_xOSO_3Na$ (x ranges from 9 to 17)

Alkyl sulfate

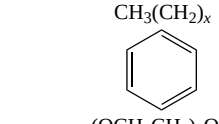
$CH_3(CH_2)_x(O-CH_2-CH_2)_y\ OSO_3Na$ (x ranges from 7 to 15); (y ranges from 0 to 6)

Alkyl ethoxy sulfate

Nonionic surfactants are also used in substantial amounts in laundry detergents and in automatic dishwashing detergents, both applications reflecting in particular their generally lower sudsing characteristics than the anionics. Commercially important examples of the nonionics include the alkyl ethoxylates, the ethoxylated alkyl phenols, the fatty acid ethanol amides, and complex polymers of ethylene oxide, propylene oxide, and alcohols.

$CH_3(CH_2)_x(O-CH_2-CH_2)_yOH$ (x ranges from 9 to 15); (y ranges from 4 to 20)

Alkyl ethoxylates



(x ranges from 7 to 13); (y ranges from 3 to 12)

Ethoxylated alkyl phenols

$CH_3(CH_2)_xCON(CH_2CH_2OH)_y(H)_z$ (x ranges from 9 to 17); (y ranges from 1 to 2); (z is 1 or 0)

Fatty acid ethanol amide

Cationic surfactants are used in only limited tonnage for specialty detergent products, such as metal cleaners for electroplating, and more commonly in ancillary textile laundering products for their fabric-softening, antistatic, and germicidal properties. A typical cationic surfactant would be tallow trimethylammonium chloride:

$$CH_3(CH_2)_{13-17}N^+(CH_3)_3Cl^-$$

In contrast with soaps, virtually all the synthetic anionic and nonionic surfactants do not form readily visible insolubles in the presence of the Ca^{++} and Mg^{++} ions present in many water supplies — the familiar scum, curd, and "lime soap" of the laundry soap era. This property, in combination with the discovery that the detergency performance of many synthetic surfactants could be greatly augmented by the addition of certain phosphate chelating agents, led to the "detergent revolution" in the laundry-product field.

Builders. *Builder* is the term used within the industry to designate materials in the synthetic detergent which chelate (sequester) or precipitate polyvalent metal ions present in the cleaning solution, particularly Ca^{++} and Mg^{++} ions, which are present in substantial quantities in so-called hard water supplies. Nearly 2 billion pounds (0.9 billion kg) of builders are presently used in detergent products, particularly in textile-cleaning detergents, where they may constitute one-half of the total weight of product. Laundry products containing significant quantities of builders are called *heavy-duty* or *built* detergents.

Builders perform several critical functions in present-day detergents:

1. They prevent polyvalent metal ions from combining with (many) surfactant(s) to form an adduct which is less effective than the unmodified surfactant in cleansing properties.

2. They prevent polyvalent metal ions from combining with various soils, such as lipid residues and clays, to form less dispersible residues, which adhere tenaciously to the surface to be cleaned.

The aforementioned effects combine to provide greatly enhanced removal of many soils and stains by a formula with builder compared with a formula without.

3. They prevent redeposition of soils removed from a surface back onto the surface through a dispersing action associated with chelating and charge-distribution effects.

4. They provide added and buffered alkalinity to the wash solution, which is generally helpful to cleansing in most applications.

5. They provide enhanced removal and kill of microorganisms, a critical property in many applications involving sanitation of commercial facilities.

By far, the most commonly used builders are the condensed polyphosphates, particularly pentasodium tripolyphosphate (STP) and, to a lesser extent, tetrasodium pyrophosphate. These polyphosphates chelate the polyvalent metal ions to form a soluble complex (under some conditions, the pyrophosphate complexes are sparingly soluble). In response to state and local legislation aimed at reducing the phosphate levels in lakes and rivers, detergent manufacturers began large-scale utilization of synthetic zeolites (sodium aluminosilicates) in 1978. Zeolites are insoluble in water, but act as ion exchange agents; exchanging Na^+ for Ca^{++} in the wash water. Peak usage of zeolites occurred in 1982 at 300 million pounds (136 million kg) annually.

Precipitating builders, such as sodium carbonate, Na_2CO_3, are also used, but to a much lesser extent, since the precipitate formed can itself deposit on the surface to be cleaned unless special washing procedures are followed. Other chelating builders than phosphates, such as trisodium nitrilotriacetate (NTA), tetrasodium ethylenediamine tetraacetate (EDTA), and other polycarboxylates, have also been used in small to moderate quantities, but questions concerning their safety, efficacy, or economics have to date prevented major displacement of the phosphates.

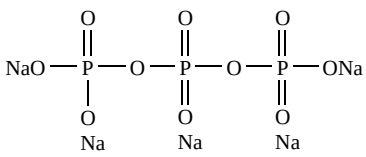
Bleaches. In many detergent applications, the action of a supplementary bleaching agent is necessary or desirable. It is frequently preferable to incorporate the bleach directly into the detergent product for reasons of convenience or performance.

Two types of bleaching agents are in common use in detergent products: (1) those based on a hypochlorite bleaching species, and (2) those based on a peroxygen species. The hypochlorite, or "chlorine," bleaches are considerably more powerful in their oxidizing action than the commonly used peroxygen bleaches under most U.S. usage conditions. Commercially important examples of hypochlorite species bleaches used in detergents include: Sodium dichloroisocyanurate dihydrate, $NaDCC \cdot 2H_2O$, and chlorinated trisodium phosphate (a physical combination of NaOCl, H_2O, and Na_3PO_4,), while sodium perborate, $NaBO_3 \cdot 4H_2O$, is by far the most commonly used of the peroxygen bleaches. All current detergent products containing bleach are dry solids since aqueous bleach solutions have not been found to be sufficiently stable in the presence of other desired detergent ingredients.

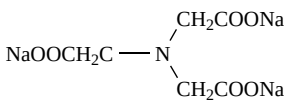
Types of detergent products to which chlorine bleaches are frequently added include hard-surface cleaners, such as the scouring cleansers and the automatic dishwashing detergents, and detergents for commercial sanitation, in which the disinfecting properties of the chlorine bleach are a critical performance attribute. In the cleaning of textiles, consideration of possible fiber and color damage prevents the universal use of a powerful oxidizing agent like hypochlorite. Consequently, a separate liquid solution of sodium hypochlorite is often used in conjunction with the detergent on those fabrics where its use is appropriate, while some textile detergents contain the milder sodium perborate bleach for more general application.

Corrosion Inhibitors. Early research indicated that unmodified alkaline detergents could be corrosive to certain hard surfaces such as aluminum, washing-machine porcelain, and the overglaze on fine china. It was quickly determined, however, that the addition of soluble silicates (silicates with varying ratios of SiO_2 to Na_2O are used, depending upon product processing and intended application) could essentially prevent this corrosive effect. Consequently, the soluble silicates are widely added in moderate amounts to alkaline detergents, and even contribute to detergency through their added alkalinity.

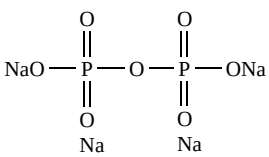
Alkalinity Boosters. It has long been known that many soils are sensitive to high pH. Fairly high levels of sodium carbonate, soluble silicates (ratio 1.6 to 3.2 SiO_2 to Na_2O) and sodium metasilicate (Na_2SiO_3) are used to supply alkalinity for improved cleaning performance.



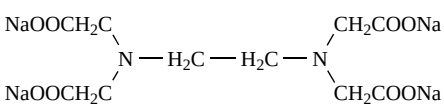
STP



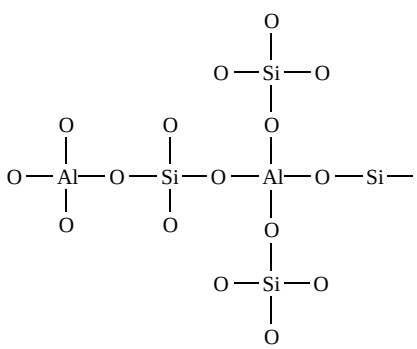
NTA



Tetrasodium pyrophosphate



EDTA



Sodium aluminosilicates
(Zeolities)

Sudsing Modifiers. In many applications, the detergent surfactants that appear to provide optimum cleansing performance do not provide satisfactory product-sudsing characteristics from a functional or aesthetic standpoint. Accordingly, materials that depress or boost the sudsing of the basic surfactant system are often added in small amounts to such products.

Examples of materials which can be used to boost the sudsing of common anionic surfactant systems are the mono- and diethanol amides of C_{10-16}, fatty acids, while the long-chain, $C_{16,22}$ fatty acids themselves and certain nonionics, such as the ethoxylated fatty alcohols, are commonly used as suds depressors.

Fluorescent Whitening Agents (FWA). Fluorescent whitening agents (also called *fluorescers, brighteners, optical bleaches*) are organic chromophores which absorb incident light in the ultraviolet region and reemit part of the absorbed energy as visible light, generally in the blue region of the visible spectrum. In addition, the chromophore is modified with organic substituents to make it substantive to one or more textile substrates from a laundry wash solution. Consequently, the brightness and whiteness of the fabrics on which FWA is deposited are enhanced. In effect, an added portion of the incident light is reflected from the fabric.

Enzymes. The most substantial advance in textile cleansing since the introduction of synthetic detergents has occurred through the introduction of low levels of enzymes into laundry detergent and presoak products. Both proteolytic and amylolytic enzymes are used by the industry to hydrolyze protein and starch so that the smaller soil fragments are easier to remove. They are effective on stains with protein and carbohydrate substituents (such as body soils, many food stains, grass stains, blood, and many others). Enzymes are catalytic and specific and thus must be used at low levels in products with excellent safety for fibers and textile colors (compared with a general chemical reactant, such as hypochlorite bleach).

Presently, all detergent enzymes are derived from fermentation cultures of specific strains of the ubiquitous bacilli *B. subtilis* and *B. licheniformis*. (The enzymes themselves are, of course, nonliving proteins, biochemical products of the bacilli which are used to hydrolyze exocellular proteins into small peptide fragments that can be absorbed by the bacteria as nutrient sources.) It had been recognized since early in this century that enzymatic action could be a most useful mechanism in textile cleansing, but available enzymes were rendered ineffective by the elevated temperatures and alkalinity required for satisfactory general detergency. The discovery and production of the *B. subtilis* and *B. licheniformis* mutants and their metabolites which remained active under laundering conditions was the essential step required to make enzymatic action available in textile detergency.

Antiredeposition Agents. In textile laundering, many soils once removed have a tendency to redeposit back onto the textile substrate during the remainder of the washing process. Certain agents, such as carboxymethyl cellulose and polyvinyl alcohol have been found to be effective in preventing or minimizing this effect and are consequently added in very small amounts to many laundry detergents.

Softeners and Anti-stats. A recent formulation trend is to incorporate fabric care benefits, such as softening and anti-static properties, into textile cleaning products in both powder and liquid form. The most common ingredient used is ditallow dimethyl ammonium chloride, the same material used in many liquid fabric-softener products:

$$(CH_3(CH_2)_{13-17})_2N^+(CH_3)_2Cl^-$$

Ditallow dimethylammonium chloride

Since this material is cationic, it is generally incompatible with anionic surfactants unless special proprietary formulation approaches are used. Therefore, fabric care detergents, especially liquids, often use nonionic surfactants.

Other Materials. In addition to the basic performance ingredients previously discussed, other materials are commonly added to facilitate product manufacture (for example, hydrotropes such as xylene sulfonate) and to enhance product acceptability among consumers (colorants and perfumes). A few materials are formed or carried along into the finished product by the manufacturing process (such as sodium sulfate and water).

Types of Detergent Products

Synthetic detergents are manufactured to perform a wide variety of household and industrial cleansing operations. Within the commercially more important (in terms of tonnage and dollar volume of sales) household-product category, the following major functional areas may be defined.

Textile Cleansing. Household laundry detergents and presoak products represent the largest single category of detergent use, currently accounting for over 2 million tons per year in U.S. consumption. These products are used in conjunction with individually owned or self-service washing machines to launder most of the clothing, bed and bath linens, curtains, and other textiles used in the typical household. Prior to the introduction of detergents over a half-century ago, soaps were almost exclusively used for these purposes.

Detergents in liquid, tablet, and granular powder forms are sold for household laundry use, the granules accounting for by far the major amount (75%) of product sold. A household laundry detergent powder typically contains 10–20% surfactant, 20–40% builder, 5–10% sodium silicates, low levels of suds builders or suppressors, anti-redeposition agents, fluorescent whitening agents, enzymes, peroxygen bleach, colorants, perfume as required to meet aesthetic and performance objectives, and the remainder being materials of processing (sodium sulfate, water). Powder bulk density varies among products, but most commonly is such as to provide a wash solution concentration of about 0.15% detergent at the product usage recommended. The presoak powders differ from the wash detergents in providing relatively higher wash water concentrations of enzymes, builders, and peroxygen bleach (if used), but a relatively lower concentration of surfactant. The liquid laundry detergents are currently the most rapidly growing segment of the market. They use the same type of materials present in powders, but typically have much higher levels of surfactants (20–30%) and lower levels of builders.

Hard-Surface Cleaning. Products used for hard-surface cleaning around the home include the hand- and automatic dishwashing products, the liquid and powder floor and wall cleaners, and the abrasive scouring cleansers.

Although the higher-sudsing laundry detergents may be used satisfactorily for hand dishwashing (and were so used extensively in the past), high-sudsing liquid products are predominantly used for this purpose. Relative to powders, the liquids offer superior ease and convenience of use, a product form into which surfactant types and levels better suited to the dishwashing task can be incorporated, and comparable economy of use since the builders required for superior laundry performance are not essential for hand dishwashing use. Dishwashing liquids typically consist of 25–45% anionic or semipolar surfactants, the remainder consisting of solvents, hydrotropes, buffers, colorants, perfumes, and water of processing. Surfactant types used in this application include LAS, alkyl sulfates, alkyl polyethoxy sulfates, di- or monoethanol fatty acid amides, alkyl glyceryl ether sulfonates, and alkyl dimethylamine oxides. The alkyl portions of these surfactants commonly average to a coconut or C_{12} chain length, as opposed to laundry detergents, where slightly longer alkyl chains are used.

Automatic dishwashing products are designed solely for use in household mechanical dishwashers, machines in which a moving high-velocity water spray is used to clean the tableware and cooking utensils. Performance requirements for an automatic dishwasher product differ substantially from those for laundry and hand dishwashing products; they include: (1) very low sudsing to prevent suds overflows with the high-velocity spray; (2) very complete rinsing to avoid residual deposits; (3) complete sequestration of Ca^{++} and Mg^{++} ions in water supplies by the use of relatively large amounts of builder to avoid deposits of sparingly soluble Ca and Mg salts; and (4) thorough removal of minute particles of food protein which can form nuclei for spot formation during drying. Consequently, automatic dishwashing products typically contain a low level of a nonionic surfactant (commonly polyoxy-ethylene/polyoxypropylene condensates), a low level of a dry bleach (KDCC or chlorinated trisodium phosphate), a high level of builder (STP and/or sodium carbonate), and moderate-to-high levels of auxiliary sources of alkalinity (sodium silicates and/or sodium carbonate). These products are typically dry powders for reasons of machine design and product bleach stability during the period between manufacture and eventual use. However, thixotropic automatic dishwashing liquid products containing bleach were recently introduced into the marketplace.

Abrasive cleaners are used to remove soils and stains from hard surfaces that are durable to the scouring action. Such surfaces include stainless steel and porcelain plumbing fixtures, metal and ceramic cooking utensils, and various stone, metal, and ceramic building surfaces. Typically, these products consist of a very high level of abrasive (commonly silica flour) with moderate to low levels of a dry chlorine bleach (KDCC or chlorinated trisodium phosphate) and low levels of surfactant (LAS) and builder (STP) for wetting action and improved stain removal.

Other hard-surface cleaners are formulated to clean larger surface areas which do not require or are less resistant to the action of an abrasive cleanser or from which the abrasive would be difficult to remove, such as floors, walls, woodwork, and large appliances. These products are sold in both liquid and powder form. The liquid products contain low levels of nonionic and anionic surfactants; moderate levels of a stable, highly soluble builder (commonly tetrapotassium pyrophosphate, $K_4P_2O_7$) for better stain removal; solvents; hydrotropes; and water of processing. The powdered products contain a very low level of surfactant (LAS), a moderate amount of builder (STP), and substantial amounts of sources of mild alkalinity (trisodium phosphate and mixtures of sodium carbonate and sodium bicarbonate) for improved soil removal. Low sudsing is a requirement for both types of products to aid in rinsing the surfaces after cleaning.

Personal Care Products. Within the broad definition of synthetic detergents, a variety of cleansing products are made for personal care. These include such products as cleansing bars, shampoos, bubble-bath products, cosmetic cleansers, and tooth pastes. Formulations of these products vary widely, depending upon their intended use.

Although essentially pure soap products continue to dominate the cleansing-bar field, a few products contain synthetic surfactants in addition to soap to act as scum and curd dispersants. Synthetic surfactants used in this application include alkyl sulfates, alkyl glyceryl ether sulfonates, alkyl esters of sodium isothionate, and alkylamides of N-methyl tauride. Shampoos are commonly formulated in liquid, paste, and gel form and usually consist of high-sudsing anionic surfactant(s) (such as LAS and those previously listed for bars), along with specific ingredients for improved hair health or control (such as antidandruff agents and substantive collagen proteins).

Bubble baths are provided in both liquid and powder form, and commonly provide a high sudsing surfactant(s). Cosmetic cleansers vary widely in formulation, depending upon intended use. Some provide mixtures of surfactants and heavy mineral oil (cold cream), while others provide an organic solvent (for mascara removal, for example). Tooth pastes provide a low level of an anionic surfactant (several types used) and high levels of a moderate abrasive (insoluble pyrophosphates), along with other special ingredients, such as anticaries agents.

Many other products, such as rug cleaners, automobile cleaners, scouring pads, and pet care products incorporate synthetic detergents.

Industrial and Institutional Applications. In addition to household products just described, a wide variety of products based wholly or partially on synthetic detergents are made for industrial and institutional use. Included among these are products that are essentially direct analogues of the various household products. In addition, there is a wide variety of products which have no counterparts among the household detergents. Included are detergents to scour raw yarns in the textile manufacturing process, detergents to clean metals prior to painting or electroplating, surgical preparation products, detergents to clean and disinfect poultry houses, and many more. Industrial and institutional detergent products account for about 500 million pounds (227 million kg) of product annually.

MANUAL G. VENEGAS AND GEORGE J. KAMINSKY,
The Procter & Gamble Company, Cincinnati, OH

DETERMINANT. A square array containing n^2 elements and said to be of order n. Let the element A_{ik} stand in the ith row and kth column of the array, then the determinant in its developed or expanded form is a homogeneous polynomial of the nth degree in these elements.

To evaluate a determinant, form all products, $n!$ in number, by taking one element A_{ik} from each row and column. The subscripts in the products, $i, i', i'', \ldots$ and $k, k, k'', \ldots$ will then include all permutations of the numbers $1, 2, \ldots, n$. Rearrange the subscripts i so that these numbers are in their natural order. The second subscripts k will then require either an even number or an odd number of interchanges to return them also to the natural order $1, 2, \ldots, n$. The value of the determinant is then defined as

$$|A| = \det A = \sum (-1)^h A_{1k_1} A_{2k_2} \cdots A_{nk_n}$$

where the summation is made over all permutations $k_1, k_2, \ldots$ of the subscripts k and h is the number of interchanges needed to restore the natural order.

Another method of evaluation is the Laplace development. Define the minor as any determinant of order $m < n$ obtained by deleting one or more rows and columns of a determinant of order n. If the row and column containing the element A_{ik} is so removed, the resulting determinant is called the complementary minor to A_{ik}. Attach the sign $(-1)^{i+k}$ to the minor and it is called a signed minor or cofactor. With these definitions, the Laplace development can be written as:

$$|A| = \det A = \sum_{i=1}^{n} A_{ik} A^{ik} = \sum_{i=1}^{n} A_{ki} A^{ki}, \quad k = 1, 2, \ldots, n$$

where A^{ik} is the cofactor to A_{ik}.

The following properties are sometimes useful in evaluation of determinants. In each case, the word *column* can always be substituted for the word *row*, or the word *row* for *column*.

1. The value of a determinant is unchanged if rows are changed into columns or if the elements of any row, multiplied or divided by a constant, are added or subtracted from the corresponding elements of another row. Its sign is changed if two rows are interchanged.

2. The value of a determinant is zero if all elements in one row are zero, if two rows are identical, or if all the elements of a row are proportional to those of another row. This property follows from the Laplace development if the i or k in A_{ik} is different from the i or k in A^{ik}.

3. If each element in any row of a determinant is the sum of two or more quantities, the given determinant can be written as the sum of two or more determinants of the same order. Thus, if $A_{ik} = a_{ik} + b_{ik} + c_{ik} + \ldots$ (i fixed), the new determinants will be identical with the old one except for the ith row and this will contain a_{ik} in the first one, b_{ik} in the next one, etc.

4. Determinants may be multiplied together by a rule similar to that used for a matrix product.

5. The partial derivative of a determinant with respect to an element A_{ik} equals its cofactor A^{ik}.

The determinant and its matrix, a closely related array, are of importance in the study of simultaneous equations. However, in any practical case, where the order of a determinant is greater than three or four, the classical methods of expansion (see also **Cramer Rule**) become prohibitively laborious and should seldom be used. Matrix methods are then much more satisfactory.

A similar procedure can also be used to evaluate a determinant. In principle, it depends on the solutions of the following equations: (1) $A_{11}x_1 = 1$; (2) $A_{11}x_2 + A_{12}y_2 = 0$, $A_{21}x_2 + A_{22}y_2 = 1$; (3) $A_{11}x_3 +$

$A_{12}y_3 + A_{13}z_3 = 0$, $A_{21}x_3 + A_{22}y_3 + A_{23}z_3 = 0$, $A_{31}x_3 + A_{32}y_3 + A_{33}z_3 = 1$; etc. Then $\det A = 1/(x_1y_2z_3\ldots)$. In practice, the work can be carried on as shown in the following form, which uses a determinant of order 3, as an example:

$$
\begin{array}{llll|ll}
 & A_{11}^* & A_{12} & A_{13} & -A_{12}/A_{11} & -A_{13}/A_{11} \\
 & A_{21} & A_{22} & A_{23} & 1 & 0 \\
\text{(A)} & A_{31} & A_{32} & A_{33} & 0 & 1 \\
\hline
 & & B_{11}^* & B_{12} & 2B_{12}/B_{11} & \\
 & & B_{21}^* & B_{22} & 1 & \\
\hline
 & & & C_{11}^* & &
\end{array}
\qquad \text{(B)}
$$

To calculate the elements B_{ij}, omit the starred row in (A) and multiply rows of (A) by columns of (B). In the same way, $C_{11} = -B_{21}B_{12}/B_{11} + B_{22}$. The value of the determinant is the product of all starred elements, $\det A = A_{11}B_{11}C_{11}$. By an obvious extension of the method, determinants of higher order can also be evaluated.

(For properties of some special determinants see also **Hessian**; **Jacobian**; **Secular Determinant**; and **Wronskian**.)

DETERMINATE STRUCTURE. Any structure in which the reactions and stresses can be found by means of the equations of statics only is a determinate structure. If a sufficient number of such equations cannot be set up from known conditions, the structure is not statically determinate.

DETONATION. See **Explosive**.

DETREND. To remove any background linear variation in a time series of data by first computing a linear regression (such as least squares best fit) to the data, and then subtracting it from the data. This aspect of conditioning data helps to remove red noise associated with a long-wavelength or long-period signal that is inadequately sampled because it is longer than the total data period of sampling.

DETRITUS. General term for unconsolidated sediments derived from preexisting rocks by natural agencies. Derived from the Latin word meaning worn.

DEUTERIC. Used by petrologists to describe those alterations in an igneous rock that occur during the later stages of its solidification.

DEUTERIUM. The isotope of hydrogen with mass number 2 is termed deuterium. The symbol D is sometimes used. Using ocean water as a reference, the atomic abundance of deuterium in natural hydrogen is 0.0149%. Deuterium oxide D_2O is known as heavy water and was first identified by Harold C. Urey in 1932. Urey noted a slight shift in the spectrum of deuterium and tritium as compared with protium (ordinary hydrogen). The diameter of the electron orbit for deuterium is slightly greater than for protium, and still greater for tritium. Deuterium and deuterium oxide gained prominence largely because of their excellent properties as moderators in nuclear reactors. See also **Uranium**.

DEUTERON. The nucleus of deuterium (heavy hydrogen) is known as deuteron. A particle that contains one proton and one neutron also is termed a deuteron.

DEUTOPLASM. Inert material stored in eggs. Yolk.

DEVELOPMENT (Photo). See **Photography and Imagery**.

DEVIATION. 1. The deviation of x from a is $x - a$. The absolute value of the deviation of x from a is defined as $|x - a|$.

2. Light passing through a prism is always deviated away from the diffracting edge if the refractive index of the prism is greater than unity. If i_1, i_2 are angles of incidence and emergence while r_1, r_2 are the corresponding angles of refraction, the deviation of the prism is given by

$$\Delta = i_1 + i_2 - r_1 - r_2$$

If the refracting angle of the prism is $\phi = r_1 + r_2$, then

$$\Delta = i_1 + i_2 - \phi$$

3. For deviation of a compass see also **Compass (Navigation)**.

DEVIATION DISTORTION. Distortion in an FM receiver caused by inadequate band-width, inadequate amplitude-modulation rejection, or inadequate discriminator linearity.

DEVITRIFICATION. The process by which the natural rock glasses, such as obsidian and tachylyte, develop minute but definite minerals, usually quartz and feldspar.

Devitrification also applies to manufactured glasses, denoting crystallization and detected by the appearance of opaque areas. See also **Vitreous State**.

DEVONIAN. The name of a geologic period. Type locality, Devonshire, England. The formations of this period were first studied and described by R.I. Murchison in 1839. The Devonian period began 330 million years ago and lasted for 50 million years. The Devonian formations are well exposed in eastern North America and parts of the North American Cordilleran. In the Appalachian Geosyncline the Devonian is largely represented by an immense thickness of red and brown shales and sandstones of deltaic and estuarine origin, and the transition between the sediments of this system and that of the underlying Silurian is so gradual that the boundary is extremely difficult to locate by physical means alone. In Britain the Devonian is represented by a marine limestone (facies) in the type locality, and a red non-marine sandstone (facies) to the north. This red sandstone (facies) is referred to as the "Old Red" by British geologists. The Scottish "Old Red" contains the famous fossil "fishes" described by Hugh Miller in 1851. These fish include two distinct groups, Ostracoderms and Ganoids, the latter being the supposed ancestors of the Amphibia or first terrestrial vertebrates. The first undoubted evidence of terrestrial plants occurs in the Devonian, the late Devonian types being the progenitors of the Carboniferous forms. In England, Scotland, Spitzbergen, western former U.S.S.R., and Norway occur great thicknesses of terrestrial, intermontane clastic sediments similar to those found in the Proterozoic. Highly fossiliferous marine sediments, including sandstones, shales and limestones, are particularly well exposed in New York State. Many of the limestone formations contain reefs composed principally of compound corals, Bryozoa and Calcareous Algae. Among the marine invertebrates goniatites and Eurypterids are particularly representative. Other common marine types are corals, Bryozoans (reefs) and Echinoderms, Pelecypods and Trilobites. The spire-bearing Brachiopods (Spirifers), which started in the Silurian, reach their maximum development in genera and species in the Devonian. The only fossil evidence of a terrestrial vertebrate rests upon a footprint (probably that of an amphibian) found in the Upper Devonian of western Pennsylvania. Beginning with the middle and ending with the period, mountain building occurred in the New England States.

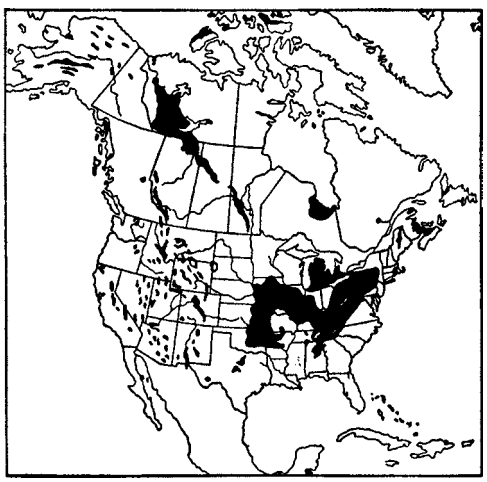

Fig. 1. Areas of outcrops (surface distribution) of Devonian, Mississippian, and Pennsylvanian strata in North America.

The principal economic products derived from the American formations are petroleum and natural gas, first exploited in 1859 in western Pennsylvania, New York, Ohio and West Virginia. See Fig. 1.

DEVONITE. The name given by Johannsen, in 1910, for a variety of porphyritic basalt containing phenocrysts of potassium-rich plagioclase. Type locality Mt. Devon, Massachusetts.

DE VRIES, HUGO (1848–1935). Hugo de Vries was a Dutch botanist, known chiefly for being credited along with Carl Correns and Erich von Tschermak for rediscovering Gregor Mendel's laws of heredity in 1900, and for later developing his own anti-Darwinian mutation theory of evolution.

De Vries was educated at the Universities of Leiden, Heidelberg and Wruzburg. He became a professor of botany at the University of Amsterdam in (1878–1918).

De Vries conducted a series of experiments hybridizing varieties of plants in the 1890s and he discovered new forms among a display of Evening Primrose *Oenothera lamarcklana* growing wild in a waste meadow. This led him to believe that evolution might be studied by a new experimental method. This new method is considered his greatest contribution to science and resulted in a new approach to evolution and a new epoch in its history. The name "mutation" was given to his new method of producing new species and varieties (cultivars) which he showed to arise unexpectedly.

He retired in 1918 from the University of Amsterdam but continued his studies with new forms. His best known works are:

- Intracellular Pangenesis (1889)
- The Mutation Theory German edition (1900-03) English edition (1910-11)
- Species and Varieties: Their Origin by Mutation (1905)
- Plant Breeding (1907) German translation (1908)

DEW. Dew forms when water condenses on objects on the surface near the ground and forms a thin layer or many droplets. Dew forms normally during the night when the air temperature decreases and approaches the dew point. Objects on the surface cool down, too, by radiative cooling, facilitating the condensation of small droplets of water. Dew formation is helped by the high humidity of the bottom layer of air, close to the surface. This layer can supply the needed water and prevent the evaporation of the dew already deposited. Strong winds can inhibit the formation of dew. Turbulence mixes a larger layer of air and creates a more homogeneous distribution of humidity and heat, thus preventing the formation of the right conditions near the ground. Dew forms more easily on surfaces that cool efficiently, like metals, which is the reason that cars are often covered with dew in the morning. But dew is often seen on grass or plants because their transpiration creates a thin layer of very humid air.

Dew is very important in the ecology of many deserts, especially those along the western coasts of Africa and South America. In some of them, water from condensation of dew caused by night cooling often exceeds that of rainfall. But dew can be an interesting source of water for human consumption, too. For instance, data recorded in the Negev desert of Israel, a country where water is really scarce, have shown that dew falls for 200 days each year. Moreover, dew is plentiful on many little islands that, surrounded by water, have high humidity but where no water dwells. Some islands of the Mediterranean Sea suffer from a chronic water shortage, which is the reason that one of the first dew-collecting plants has been built in Ajaccio (Corsica Island in France). It is also interesting to describe an old project studied in India and unfortunately never actually realized. The idea was to pump water at 4.5 °C (40.1 °F) from the sea at a depth of 500 meters (1,640 ft). The pumping scheme called for the use of four 1.2-meter (4 ft) pipes and wind-powered pumps. A heat exchanger of 130,000 square meters (1,399,308 square ft) could then condense, every day, more than 600 cubic meters (21,189 cubic feet) of dew.

But many animals and plants have already learned how to survive on dew. A place particularly interesting for this kind of adaptation is the Namib desert in Namibia (Africa). Here, many insects in the early morning sit on top of sand dunes trying to catch some dew (or fog) on their wings and legs. In particular, the beetle *Stenocara* has even modified the surface of its hard shell surface to trap mist more efficiently. This beetle shell is covered with bumps whose peaks are smooth like glass and attract water. The troughs around the bumps are covered with a wax that repels water. The water is therefore collected by the peaks, and when a droplet is big enough to touch the water repelling valley it rolls down to the animal's mouth. Some researchers think that the easy trick of the animal can be used in dew collecting devices. A similar surface can be prepared in many ways, even with an ink-jet printer that sprays hydrophilic ink onto an acetate sheet. Dew-collecting devices have the problem of making the water run off the collecting surface.

Another Namibian creature well adapted to survive on dew is the plant *Welwitschia mirabilis*. Despite its look, it is a close relative of pine trees. It has a short trunk split in two and from each side grows a single leaf that can be several meters long. Welwitschias are among the oldest plants on the earth, and some of them are 1500 years old. The trick that allows this plant to survive in one of the driest deserts of the planet is a two-part root system. Welwitschias have a long root that goes deep in the soil trying to reach the water table and extends for several meters away from the plant. These roots collect all the dew that forms on the top layer of soil. Moreover, all the water that condenses on the leaves forms big drops that eventually run down, so that the plant can water its own roots.

ALDO CONTI, Frascati(RM), Italy

DEWAR FLASK. A vessel with a double wall, in which the region between the walls has been evacuated, and in which the walls bordering this space have been silvered. With this construction the region within the inner container is very well insulated from the outside. The vessel is commonly used for storage of liquefied gases, and a similar device is used widely for hot or cold beverages.

DEWBOW. A rainbow formed in the small drops often found on grass in early morning. While the name implies that those drops are dew, as a practical matter, that is probably rarely the case. Rather, the drops are usually the result of guttation rather than dew. When seen stretched across a meadow, the dewbow may appear in the shape of a hyperbola, but that is merely the intersection of the cone of light that forms the bow and the surface of the meadow. Because they are seen against a surface, dewbows sometimes are perceived as hyperbolas even though, like ordinary rainbows, they are arcs with a constant angular radius. See also **Atmospheric Optical Phenomena**.

DEW CELL. A type of hygrometer used to determine the dewpoint. The equilibrium vapor pressure at the surface of a saturated salt solution is less than that for a similar surface of pure water at the same temperature. This effect is exhibited by all salt solutions but particularly so by lithium chloride. The dew cell hygrometer works in the following manner: The lithium chloride solution is heated until a temperature is reached at which its equilibrium vapor pressure exceeds the ambient vapor pressure. At this point the balance will shift from condensation to evaporation, which can be detected by a characteristic decrease of the conductivity of the solution. By properly regulating the heating current, the equilibrium temperature can be transformed by means of empirical equations to the ambient water vapor pressure and the dewpoint. Provision is not usually made for cooling the dew cell, and consequently it will not measure vapor pressure less than the vapor pressure over saturated lithium chloride solution at the ambient temperature. Dew cells are used for observational purposes, especially for automatic weather stations. See also **Precipitation and Hydrometeors**.

DEW CLAW. Small hoofs of the rudimentary toes, found just above the functional hoofs in some of the even-toed hoofed animals.

DEWLAP. The fold of skin which hangs below the neck in cattle.

DEWPOINT. The temperature to which a given air parcel must be cooled at constant pressure and constant water vapor content in order for saturation to occur. Any further cooling usually results in the formation of dew or frost. Also called *dewpoint temperature*. When this temperature is below 0 °C (32 °F), it is sometimes called the *frost point*. The dewpoint may alternatively be defined as the temperature at which the saturation vapor pressure of the parcel is equal to the actual vapor pressure of the contained water vapor. Isobaric heating or cooling of an air parcel does

not alter the value of that parcel's dewpoint, as long as no vapor is added or removed. Therefore, the dewpoint is a conservative property of air with respect to such processes. However, the dewpoint is nonconservative with respect to vertical adiabatic motions of air in the atmosphere. The dewpoint of ascending moist air decreases at a rate only about one-fifth as great as the dry-adiabatic lapse rate. The dewpoint can be measured directly by several kinds of dewpoint hygrometers or it can be deduced indirectly from psychrometers or devices that measure the water vapor density or mixing ratio.

DEWPOINT FORMULA. A formula for the calculation of the approximate height of the lifting condensation level. Therefore, it is employed to estimate the height of the base of convective clouds, under suitable atmospheric and topographic conditions. In a practical but simplified form, it may be stated

$$H = (T - T_d)/8$$

where H is the height above the surface in km and T and T_d are the temperature and dewpoint in degrees Celsius. This is derived from assuming that the temperature decreases 9.8 °C and the dewpoint decreases 1.8 °C for each km increase in altitude, values which are approximately correct for a well-mixed boundary layer. The convective-cloud height diagram is a graphic form of this relationship.

DEZINCIFICATION. A form of electrolytic corrosion observed in some brasses where the copper-zinc alloy goes into solution with subsequent redeposition of the copper. The small red copper plugs thus formed in the brass are usually porous and of low strength. In recent years, the term dezincification has also been applied in a more general sense to signify any metallic corrosion process that dissolves one of the components from an alloy.

DIABETES INSIPIDUS. Characterized by the passage of large quantities of urine (polyuria) and usually accompanied by excessive thirst, diabetes insipidus is caused by the absence or insufficiency of vasopressin (antidiuretic hormone). Vasopressin and oxytocin are secreted in the hypothalamus. They are transported along the axons of the neurons and stored in the posterior pituitary. The posterior pituitary is composed of the terminal portions of neurons whose origin is in the hypothalamus. See also **Pituitary Gland**.

A mild insufficiency of vasopressin may cause partial diabetes insipidus that may not require treatment unless the condition (polyuria) interferes with sleeping. The disease usually has a sudden onset and the patient will exhibit a strong preference for iced drinks. The diagnosing physician will rule out vasopressin resistance arising from significant renal disease as well as compulsive water drinking (a psychogenic disorder). The most recent diagnostic tool is direct measurement of plasma arginine vasopressin. Where polyuria interferes with sleeping, chlorpropamide, which potentiates the effect of vasopressin on renal concentrating ability, may be prescribed, but only in the confirmed absence of anterior pituitary insufficiency. In more severe cases of diabetes insipidus, vasopressin tannate may be administered intramuscularly every few days. More recently available in some countries is an analogue of vasopressin, known as DDAV.

In Pregnancy. Because of the pressure that an enlarging uterus has on the adjacent bladder during pregnancy, this sometimes alters the woman's pattern of voiding. There is a more frequent urge to void and to pass smaller volumes of urine at a time. This is regarded as a normal consequence of pregnancy. However, when there is polyuria (excretion of large amounts of urine), where thirst is excessive with accompanying intake of large volumes of fluid (polydipsia), there is reason to suspect a pathological condition. As pointed out by Robinson and Amico (reference cited), "Diabetes can cause these symptoms, but the suspected form is usually mellitus, not insipidus. The latter is rare and, when present, it challenges both the diagnostic and therapeutic skills of clinicians."

Diabetes insipidus in pregnancy may be transient. By way of a poorly understood pathway (high plasma vasopressinase activity), is complex and much too detailed to be described here, but is well elucidated in the aforementioned reference. Although the physiologic consequences of the lowered thresholds for thirst and vasopressin secretion in pregnant women can be described, there is little understanding of the adaptation that occurs in the neurons controlling these responses. However, the changes in water homeostasis and vasopressin metabolism that occur during normal pregnancy provide an explanation for the transient expression of diabetes insipidus (sometimes called "non-sweet diabetes") in pregnant women.

DIABETES MELLITUS. Awareness of this disease dates back to 1500 B.C. The term *diabetes* was first used in the second century A.D., and expanded to *diabetes mellitus* in the sixth century A.D. In a very general way, the disease can be described as a serious metabolic disturbance, with numerous accompanying complications. Although in most diabetics there is considerable parallelism of symptoms, there also are many differences, particularly in the degree to which complications occur. Much has been learned about diabetes mellitus during the past few decades, including postulations at the molecular level and the probable role of genes in determining heritable factors in some cases.

Perhaps science may be approaching possible breakthroughs in understanding and is closer to a long envisioned cure for the disease, but it is essentially unrealistic to project possible future successes. With proper medical care, accompanied by the interest and cooperation of the patient, the life of many diabetics has been extended to old age, but this is not universally true because of the many nuances of the disease that in major or minor ways characterize each individual case of diabetes mellitus. When these biochemical nuances are combined with such statistical factors as age of onset and type of care and therapy (if any) used (such as diet, exercise, and environment), group studies of patients are difficult to formulate and to interpret. Obviously, there are many subclasses of diabetes mellitus, yet the professionals in the field employ only two very coarse classifications, namely:

Type 1 — IDDM (Insulin-Dependent Diabetes Mellitus)
Type 2 — NIDDM (Non-Insulin-Dependent Diabetes Mellitus)

Although very useful, these broad classifications do not embrace the specific complications of the disease, including *retinopathy*, which impairs vision and can lead to blindness; *neuropathy*, which involves nerve degeneration and peripheral vascular problems; and *nephropathy*, which causes kidney damage and can lead to renal failure.

Effective control of diabetes mellitus not only prolongs lives for many years, representing a tremendous human and economic savings, but also can often delay or eliminate the aforementioned debilitating and costly end stages of complications. Unfortunately, even in the most advanced countries, thousands of diabetics remain undiagnosed because of the lack of sufficient screening programs. As is the case with many diseases which progress very slowly, persons who are medically illiterate and do not have physical examinations for other reasons, such as requirements for employment, will escape detection until such time that they seek help in connection with one of the complications of the disease; thus, individuals can be diabetic for years without knowing it. Unfortunately, the early symptoms are not exclusive to the disease and can be passed off as just feeling poorly, but not knowing why. This is, in a way, ironic because a glucose tolerance test is so easy and inexpensive to make. The foregoing remarks apply mainly to Type 2 diabetes mellitus, as contrasted with the Type 1 disease, which is early onset (children and youths) and with more severe life-threatening symptoms. However, in countries that do not have adequate child health care programs, individuals can die before diagnosis.

The number of diabetics in the United States alone is estimated between 3.5 and 4.7 million, not including large numbers who are undiagnosed. Direct and indirect cost attributed to the disease in the United States is estimated at well over $5 billion. Similar statistics when scaled against total population apply to numerous other countries, especially the United Kingdom and Europe. In the United States about 1.7 million people, including over 100,000 children, are diabetics who take insulin daily. Approximately an equal number of diabetics take oral hypoglycemic

agents, and another 2 to 3 million people control their disease by dietary measures.

General Mechanisms of Diabetes Mellitus

In a nondiabetic, plasma glucose level is maintained automatically by a very complex, still rather poorly understood network that not only involves the important hormone, insulin, but which also includes other hormones, neurotransmitters, and substrates. Some of these substances regulate glucose levels; others are antagonists. In the nondiabetic, the substances appear to achieve a proper balance. In the diabetic, in contrast, external intervention is needed to strike a proper balance, whether this balance be achieved strictly through diet control or by the administration of externally prepared insulin. In the nondiabetic, the insulin delivery system is geared essentially in proportion to food intake. In insulin therapy, important controls must be made manually. The timing and quantity of meals, the dosage strength and frequency of the insulin must be carefully programmed to the needs and characteristics of each individual. The insulin-dependent diabetic must follow a strict daily regimen and also know how to handle unusual situations when patterns may be temporarily altered. This requires frequent urine or blood tests, self-administered by the patient, and very close cooperation with the physician. Usually, a considerable time span is required to establish the most satisfactory regimen.

It should be stressed that insulin therapy is directed toward making up for an insulin deficiency and is not addressed to the entire metabolic problem that is presented by diabetes mellitus. Until much more knowledge is gained about the interworkings and mechanisms of the disease, however, either diet control and/or insulin therapy will remain the solutions of choice.

A very important factor in insulin therapy is what might be called the negative image of hyperglycemia, namely, an abnormally low glucose level, *hypoglycemia*. It is obvious that if the desired glucose level is midway between hyper- and hypoglycemia, a disproportionate correction of the one condition will lead to the other condition. Hypoglycemia is rather frequently encountered in insulin-dependent diabetics and sometimes, to a lesser extent, in diet-controlled diabetics. Because of the brain barrier, described in a separate article in this encyclopedia, the brain and central nervous system cannot use fuels other than glucose. The brain cannot synthesize nor can it store more than a few minutes' supply of glucose. Too little glucose causes brain death when the condition is severe and prolonged. Even moderate hypoglycemia can cause substantial cerebral dysfunction of a threatening nature.

Forms of Diabetes Mellitus

As previously mentioned, there are two basic classes of the disease.

Insulin-Dependent Diabetes Mellitus. This form results from the *destruction* of beta cells by viral or autoimmune processes, or both. IDDM most often develops in childhood or adolescence. Thus, it was once called juvenile-onset diabetes. Other accepted terms for IDDM today include *ketosis-* or *acidosis-prone diabetes*, or simply *Type 1 diabetes*. Ketoacidosis is a major consequence of poorly managed IDDM. Of all diabetic patients, only 5 to 10% present the IDDM form.

Non-Insulin-Dependent Diabetes Mellitus. This form is characterized not by full destruction, but by a *gradual decline* in beta cell function. NIDDM usually is first diagnosed in middle or later life. Thus, it was once called maturity-onset diabetes. Other accepted terms for NIDDM today include *ketosis-* or *acidosis-resistant diabetes*, or simply *Type 2 diabetes*. A high percentage of patients with this form of diabetes are overweight at the time of initial diagnosis. Of all diabetic patients, the majority (90–95%) present the NIDDM form.

Overlapping Forms. There may be some overlap between the two forms of diabetes. Infrequently, IDDM may go into remission and insulin may no longer be required. In such instances, when insulin therapy is halted, the patient does not experience ketoacidosis. Also, relatively infrequently, NIDDM may worsen to the extent that the patient, who formerly depended exclusively on diet control of the disease, may have to turn to insulin therapy — not just to control blood glucose values, but also to prevent ketoacidosis. This condition may occur even in situations where a patient has augmented diet control with oral hypoglycemic agents.

Physiology and Biochemistry of Diabetes Mellitus

The Pancreas. The physiology and disorders of the pancreas as related to matters other than diabetes mellitus are described in the entry on **Pancreas**. The pancreas gland contains *acnar cells*, which manufacture digestive enzymes for secretion into the duodenum; and groupings of cells known as the islets of Langerhans, which secrete a variety of hormones, including insulin, into the bloodstream. These islets, first discovered by Paul Langerhans over a century ago, are involved in the melange of metabolic and metabolically induced disorders commonly called diabetes mellitus. It has been estimated from micrographic techniques that there are between one and two million such islets in the pancreas. They are about 200 microns in diameter and make up only about 2% of the mass of the gland. They are generously vascularized. Research to date indicates that there are at least four kinds of cells in each islet. The cells have been differentiated as to function. (1) The hormone *glucagon* is secreted by alpha cells, which constitute about 20% of the islet. (2) The hormone *insulin* is secreted by beta cells, which account for about 75% of the islet. (3) The delta cells, comprising less than 5% of the islet, secrete the hormone *somatostatin*. (4) The PP cells, also comprising less than 5% of the islet, secrete *pancreatic polypeptide hormone*.

Insulin from the beta cells is known to regulate carbohydrate and fat metabolism, especially glucose oxidation. It also stimulates amino acid and glucose transport into cells and protein synthesis. Insulin mediates the uptake of glucose by liver, muscle, and fat cells and the conversion of glucose to glycogen in these cells.

Glucagon from the alpha cells, also known as the HGF factor (hyperglycemic-glycogenolytic factor), is known to increase blood sugar, blood potassium, oxygen consumption, liver glycogenoloysis, gluconeogenesis, and nitrogen and salt excretion, while it decreases liver glycogen, protein formation, gastric juice, and fatty acid synthesis. Glucagon is antagonistic to insulin and reverses the actions effected by insulin.

Somatostatin from the delta cells is known to inhibit the secretion of both insulin and glucagon. The role of pancreatic polypeptide hormone released by the PP cells is still poorly understood.

The sequence of events occurring in the pancreas and associated organs, greatly simplified, proceeds about as follows:

(1) The ingestion of carbohydrates and proteins causes the beta cells to respond directly to the rise in blood glucose and amino acids. This response takes the form of secreting increased insulin. This response is governed both by amount and rate. Where insulin furnished is deficient or too slow, the blood glucose level will remain high for an appreciably longer period of time. In diagnosing diabetes mellitus, physicians employ a glucose-tolerance test as illustrated and explained by Fig. 1.

(2) The liver is alerted by the higher insulin level, — chemically sensing that a supply of fuel (food) is on the way. In a reverse (fasting) situation, low insulin levels signal an inadequate fuel supply.

(3) By way of a process still not fully understood and occurring simultaneously with the build-up of insulin level, chemical signals from the enteric system (in the form of pancreozymin or cholecystokinin) enter the blood, these substances also stimulating the beta cells to increase insulin secretion. There appears to be a quantitative relationship between these signals and the amount of fuel introduced into the system.

(4) Still unproved, but strongly suspected, is the concept that the gastrointestinal inhibitory peptide (GIP) and pancreozymin are coded — so as to respectively designate ingestion of carbohydrate and/or protein.

(5) Alpha cells, also responsive to blood glucose and amino acid concentrations, secrete more or less glucagon. A low level of glucose increases glucagon secretion. A high glucose level suppresses it. Where both glucose and amino acid levels increase, the response to glucose predominates, causing glucagon to decrease.

(6) Increased glucagon initiates a response by the liver for increased glycogenolysis. Decreased glucagon deaccelerates the process. See also **Liver**.

The liver functions in the "fed" state to consume glucose for the synthesis of glycogen and fat, while using some of it to furnish its own energy needs. In the total process, glucose not only is utilized by muscle for energy and for the synthesis of glycogen, but also is used by adipose tissue for the synthesis and storage of fat. Insulin inhibits the release of free fatty acids from adipose tissue. Thus these acids in the blood are significantly reduced during the "fed" state. Central to the success of these metabolic processes is the optimal maintenance of insulin: glucose: glucagon proportionalities at all times.

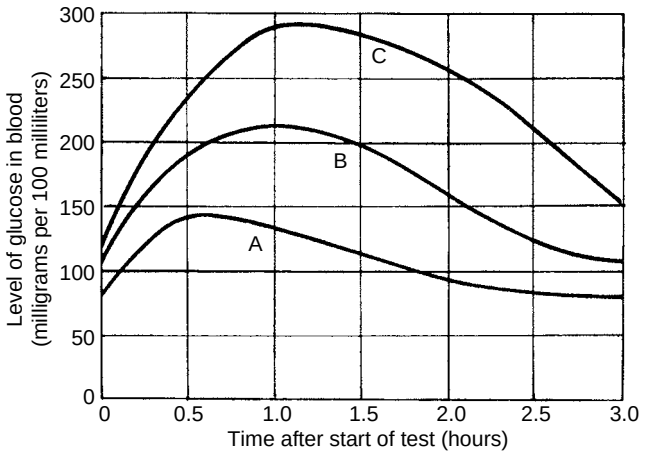

Fig. 1. In a glucose-tolerance test, the patient consumes a flavored drink that contains exactly 100 grams of glucose. The blood glucose is measured before the start of the test (time = 0) and at one-hour intervals up to a total of 3 hours. The patient is directed to fast for a period prior to start of the test. Curve A indicates response of a normal, nondiabetic person. Curve B indicates an impaired glucose tolerance, but not quite that of a diabetic. Curve C is typical response for a diabetic, demonstrating how the glucose level, after peaking, remains at an elevated level even after three hours. In normal persons, the glucose level is below 160 milligrams per 100 milliliters after one hour of eating a normal meal (or glucose load given in the test); and a level of 120 mg/100 ml two hours later.

Carbohydrate metabolism and fat metabolism are further described in the entries on **Carbohydrates**; and **Lipids**, respectively.

In diabetes mellitus, one of at least three situations may be present: (1) essentially no natural insulin is available; (2) natural insulin is available, but not in sufficient quantity to handle a normal diet; and (3) according to a relatively recent concept, natural insulin is available, but is not effectively utilized because of malfunctioning or sluggish receptors. Situations (2) and (3) may be present together. Considering the vast number of cells in the body to be served by a markedly reduced number of beta cells, it becomes obvious why increased weight over normal (obesity) antagonizes the disorder. It is also evident why patients are frequently advised to eat less per meal and more often, thus spreading out the demand for insulin during the day rather than concentrating that demand three times per day.

A situation of severe insulin insufficiency, in terms of system responses, marks the fasting (starving) state and the system, recognizing this as an emergency, activates all elements of the system, particularly the liver, to adjust to it. Muscle tissue releases amino acid at an accelerated rate; free fatty acid is released from adipose tissue at an enhanced rate; hepatic (liver) uptake of amino acids and free fatty acids is accelerated; production of glucose and keto acid by the liver is maximized. Thus, although not in need, the body is furnished with fuel in excess. This is reflected by a marked rise in blood glucose levels. In this state, grossly damaging consequences occur if the patient is not immediately treated. High levels of glucose in the urine (glucosuria) and high levels of ketones in the urine (ketouria) initiate polyuria (large quantities of urine), leading to dehydration, hypovolemia (blood loss) and, within a day or two, death. The latter phases of this chain are called *diabetic coma*.

Ultimate Consequences of Diabetes Mellitus

The fundamental metabolic dysfunction of diabetes mellitus causes, over varying time spans, a number of debilitating disorders. Of these, the three disorders most commonly encountered are:

1. Retinopathy (ocular);
2. Neuropathy (neural); and
3. Nephropathy (renal).

Some treated diabetics may not suffer any of the foregoing consequences and ultimately die of other essentially unrelated causes. But a majority of patients will exhibit symptoms of any or all of the foregoing debilitations, ranging from relatively minor manifestations to the ultimate loss of life from one of these consequential disorders. There are additional consequences where the connection to diabetes mellitus remains poorly understood. The fact that cannot be overstressed is the *individualistic* nature of the disease, which does not progress in a uniform manner among patients in terms of time or consequences.

The aforementioned three consequences, however, appear to share a common root cause physiologically — namely, that the tissues (lens, nerves, and kidney) are not dependent on insulin. Biopathways to these organs are commonly affected by the "diabetic state" as well as by anoxia and a variety of drugs.

Retinopathy. Estimates indicate that 5000 patients with diabetes in the United States and from 30,000 to 40,000 diabetics worldwide become legally blind each year from retinopathy. The statistics remain high, even though advanced treatment techniques, such as photocoagulation and vitrectomy, are in place. Diabetic retinopathy persists as the leading cause of blindness in North America, Europe, and Great Britain.

Studies of the complex biochemical pathways that lead to retinopathy are continuing. Currently, much is known in a qualitative way, but the ultimate comprehension of the disorder may have to await research findings at the molecular level.

The biochemistry obviously is quite complex and much too detailed for coverage here. An excellent summary, however, is given in the Merimee reference listed. In the conclusion to this article, Merimee (University of Florida School of Medicine) observes, "The task confronting physicians today remains much the same as it was 50 years ago: to control hyperglycemia as persistently and effectively as possible, while keeping in mind that some patients may have transient progression of their retinopathy even when glycemic control is achieved. This emphasis does not neglect current insights into the mechanisms responsible for diabetic retinopathy, although it does reflect our inability to intervene effectively in other ways." See also **Vision and the Eye**.

Neuropathy. This disorder usually commences in the feet and legs of the diabetic, but the process, which affects the peripheral nerves, may progress for years without symptoms. Early symptoms include pain and coordination of voluntary muscular movements (ataxia), among a variety of other syndromes. These disorders are not exclusive to diabetics, but may arise from other causes. In what is called the carpal tunnel syndrome, there are episodes of prickling in the fingers and pain in the hands, frequently triggered by excessive repetitive movements (sewing, wrist flexing).

As pointed out by Dyck (Mayo Clinic), "The cause or causes of the diabetic neuropathies remain unknown. Because prolonged hyperglycemia (i.e., lasting for years) appears to precede the development of polyneuropathy, one assumes that metabolic derangements (flux through the polyol pathway, a deficiency of *myo*-inositol or sodium-potassium-adenosine triphosphate, or excessive glycation of proteins, for example) may be responsible. Whether these metabolic changes affect the nerves directly or by altering microvessels is an important question."

As previously mentioned, the particular expressions of polyneuropathy in diabetics is varied within a class of patients and thus is quite individualistic in its manifestations. There are, however, two broad symptomatic classifications:

1. *Pain*, which is due to hyperactivity of damaged or degenerated axons and
2. *Axonal hypofunction*, including muscle weakness and sensory loss (including the sensations of cold, warmth, and even pain). In connection with sensory loss, there are numerous risks, such as injuries and infection of the feet and lower extremities, leading to a lack of normal attention given to cuts, bruises, and even burned tissue. The diabetic so affected, consequently, must pay particular attention to regularly inspecting and caring for the feet to prevent plantar ulcers of the foot and Charcot's joints of the ankle, as examples.

As pointed out by Dyck, "Most people with diabetes do not have neuropathic pain. However, when it occurs, it may have a monophasic course (e.g., in proximal asymmetric neuropathy or truncal neuropathy) in which pain usually lasts only weeks or months."

Minor improvement in nerve conduction velocity has been demonstrated in short-term studies of patients undergoing intensive-intermittent insulin therapy. Also, the effects of pancreatic transplantation on diabetic polyneuropathy have been studied. The findings suggest that the progression of diabetic polyneuropathy can be halted and slightly improved by successful pancreatic transplantation. However, the degree of improvement noted is quite small, probably because of prior structural damage to the peripheral nervous system. The effect of pancreatic transplantation may be greater if

it is performed at an earlier stage of the disease. More details are given in the Kennedy reference.

A closely allied topic is *peripheral vascular disease*, which ultimately occurs in about 30% of diabetes mellitus cases. The risk of being affected by this disorder, which also arises from several nondiabetic causes, is, in the diabetic, at least five times that of the general population. This disease may progress to the point where amputation of a limb may be required for the patient's survival. More detail is given in the excellent Coffman reference listed.

Nephropathy. Diabetic nephropathy (glomerulosclerosis of the kidney) today is the most common cause of end-stage renal disease. See also **Kidney and Urinary Tract**. The late signs of the disease are progressive loss of glomerular filtration rate and heavy proteinuria (excessive protein in the urine, usually albumin). It has been known for many years that in insulin-dependent diabetics the glomerular filtration rate increases early in the course of the disease and that many patients have enlarged kidneys. These conditions, however, do not necessarily lead to nephropathy. As with so many of the disorders frequently associated with diabetes mellitus, nephropathy is not exclusive to diabetics, but can arise from other causes in nondiabetics.

To date, the pathogenesis of diabetic nephropathy is poorly understood. Nephropathy develops in only 40% of diabetic patients. Some qualitative factors are known. One hypothesis is that the diabetic "state" alters the circulation or tissue levels of hormones that affect growth. It is known that growth hormone can induce renal hypertrophy. This hypothesis is explained in the Gluck-Klahr reference listed.

Wilson and Leutscher (Stanford Medical Center), in a study of over 30 patients, found that microalbuminuria may predict incipient nephropathy in Type 1 diabetes. Inasmuch as diabetic complications are uncommon in young diabetics, but develop as they enter adolescence, early detection can be valuable. Renin, which is secreted into the blood by certain kidney cells, derives from a larger precursor, *prorenin*. Thus, by monitoring prorenin levels, one can assess risks of complication of diabetes well in advance, a technique of particular advantage in the case of young patients. About one-quarter of Type 1 patients present overt albuminuria, indicative of nephropathy that may progress to end-stage renal failure.

The Nature of Insulin

The principal drug used for the treatment of diabetes mellitus, *insulin*, is a polypeptide. See also **Protein**. These compounds are composed of varying numbers of amino acids (i.e., compounds containing at least one amino group and at least one acid (carboxyl) group).

Insulin has a molecular weight of approximately 6000 and thus is considered a large peptide, bordering on being a protein. Individual insulin molecules (monomers) are inclined to congregate in groups, consisting of two or six individual monomers, thereby forming dimeric or hexameric insulin structures. Insulin is a hormone secreted by the beta cells of the pancreas and consists of two separate amino acid chains.

The manner in which insulin is assembled was first suggested by D.F. Steiner and coworkers at the University of Chicago in a classically designed experiment in the 1960s. Essentially, their technique involved immersing beta cells in various amino acids that had been tagged with radioactive isotopes. The tagged proteins then were separated, analyzed, and identified using chromatography. Then high-resolution autoradiography was used to determine the precise location of the proteins within the beta cell.

It was learned that the production of insulin starts in the beta cell nucleus, where the gene encoding the precursor molecule (preproin) is transcribed into RNA. The following complex process, much too detailed to describe here, is explained in the excellent Orci paper listed, which ends with the conclusion, "We have described the intracellular journey of insulin from the site of its synthesis (the rough endoplasmic reticulum), to the site of its release (the beta-cell membrane). Throughout this journey, the critical roles played by the Golgi apparatus and the clathrin-coated secretory granules in the sorting and processing of proinsulin have been evident. Many questions remain unanswered, but the information accumulated in recent years on the general layout and assembly line of the insulin factory (in humans) has opened the way to a fuller understanding of hormone secretion and its regulation in molecular terms."

The fact that diabetes widely occurs is de facto evidence that in many people the *human insulin factory* is dysfunctional.

Chronological Perspective. O. Minkowski and Baron Joseph von Mering, physicians of Strasbourg in 1889, removed the pancreases from several dogs in an effort to find out if that gland was essential to life. The researchers were surprised to find that flies were attracted to the canine urine. The urine was analyzed and found high in glucose content. Thus, the first recorded association of the pancreas with glucose metabolism was established.

The search for an antidiabetic substance, presumed to be secreted by the pancreas, was commenced about 1909, and even before such a substance was discovered and identified, it was given the name insulin. Early attempts to treat pancreatectomized dogs with crude pancreas extract given orally to the canines proved unsuccessful, and the failure was later explained on the basis that the extract (a protein) was destroyed by protein-cleaving enzymes in the gastrointestinal tract. Canadian investigators Banting and Best later extracted insulin from dog pancreas and found that injection of the insulin into diabetic dogs reduced the glucose level of the canine blood quite promptly. This experiment led within a few years to the use of insulin extract in human subjects, a practice which, with improvements, continues in use by many diabetics today. The experiment was highly publicized and for awhile it was believed that a "cure" for diabetes mellitus had been achieved. The administration of insulin did ameliorate the primary symptoms of the disease, including death from coma, but several years later it was found that insulin did not cure the many serious long-term complications of the disease.

Sources of Insulin. As described by Barfoed, "There is little difference in the composition of insulin from different animal species. Insulin from humans and from many animals, such as pigs, cattle, sheep, and rabbits, consists of 51 amino acids arranged in two chains. The A chain has 21 amino acids and the B chain has 30 amino acids. The A and B chains are connected by two disulfide bridges in the insulin molecule."

Natural human insulin differs from beef insulin by three amino acids (#8 and #10 in the A chain and #30 in the B chain). Pork insulin and human insulin differ from each other in only one amino acid (#30 in the B chain). These small differences probably have accounted for the success in using either bovine or porcine insulin in the treatment of human diabetes mellitus.

In manufacturing animal insulin, the pancreas is removed immediately upon slaughter of the animal, after which it is refrigerated at a temperature of about $-20\,^{\circ}\mathrm{C}$ ($-4\,^{\circ}\mathrm{F}$) to prevent damage by enzymatic action. Small pieces of pancreatic tissue then are placed in an extraction vessel that contains ethanol acidified to a pH of about 2 through the addition of hydrochloric or sulfuric acid. Under these conditions, pancreatic trypsin is inactive and is separated from the insulin solution, after which the solution is neutralized.

Inasmuch as insulin is damaged by elevated temperature, low-temperature vacuum evaporation is used to concentrate the neutralized extract. Fat and protein compounds then are filtered out of the solution and salt is added to the purified solution, causing the insulin to precipitate out as *salt cake*. This is dissolved in a small portion of acidified pure water, and the insulin is precipitated out, once again, by adjusting the pH value of the solution to the isoelectric point of insulin. Following is a series of purifying recrystallizing operations.

Prescription insulin is purified chromatographically. The objective is to produce an insulin so pure that normally occurring impurities are well below limits of detection with assay methods. After this purification, the insulin, once again, is crystallized, after which the crystals are dried and various batches are mixed and analyzed. Individual formulations then are prepared in the forms of *short-acting*, *intermediate*, and *long-acting* preparations, as may be prescribed by treating physicians.

Long-acting preparations have been available since the 1930s,[1] when it was found that protamine (a protein extracted from the sperm of salmon and trout) made the insulin less soluble. This made it possible to establish by injection a "cache" of insulin in the body around the injection site, available for slow release into the blood stream. It was found later that zinc, a component of protamine, produced the same effect. *Insulin preparation*, covering a range from short- to long-acting preparations, is effected by mixing solutions of different profiles.

Early insulins were linked with certain side effects in some individuals, causing immunologic and/or allergic reactions. These reactions were

[1] *Novo Industri A/S*, Denmark.

markedly lowered when crystalline insulin was introduced in the 1940s. However, antibodies still were present, even though the insulin had been purified through several crystallizations. Improved analytical methods revealed that what was *apparently pure* insulin did indeed contain up to several percent of different impurities, of which proinsulin was the main component. Processing continued to improve up to the point where a product referred to as *monocomponent insulin* (MC) became available. To a greatly reduced extent, even the MC insulin can cause infrequent allergies in animal-based insulin. This was sufficient incentive for the makers to seek even better ways of producing a pure insulin product.

What methods were available to produce pure human insulin and avoid bovine and porcine sources as starting ingredients? These methods included total organic synthesis, which, although technically feasible, would be very complex and costly, considering the intricacies of insulin structure. Another way would be the use of fermentation in connection with genetically engineered microorganisms. Still another way would be to commence with porcine insulin, but through chemical processing, transform the porcine insulin molecule into an exact replica of the human insulin molecule. Currently, a so-called "human" insulin is processed along these lines.

Another step toward human insulin is a fermentation process into which microorganisms genetically coded for insulin are introduced. The process represents the essence of modern biotechnology. The human insulin end product is produced by a one-step enzymatic conversion, avoiding the extensive use of chemicals and chemical processes used by earlier recombinant DNA methodologies. More detail can be found in the Barfoed reference listed.

Insulin Resistance/Receptors. Because of several conflicting findings concerning diabetes mellitus and the diseases which it induces, a consensus has developed in recent years that the condition is a rather heterogeneous group of diseases, or indeed a multifaceted disease which, in either case, leads to an elevation of the glucose level of the blood. Research, particularly during the last few years, has shown that the pancreas of many Type 2 diabetics produces ample quantities of insulin. There is, however, a reduced sensitivity of fat and muscle cells to the effects of insulin, a phenomenon sometimes called *insulin resistance*. The mechanics of this phenomenon still are not well understood, but a breakthrough was achieved in 1971 when the insulin receptor from rat liver membranes was first isolated by researchers at Johns Hopkins University School of Medicine.[2] The isolation of hormones is a very tedious and exacting procedure.

A bit later, other researchers at Georgetown University Medical Center isolated glucagon receptors. This earlier research cleared the way for studying the characteristics of insulin binding. Studies have been conducted in the United States and other countries in which obese mice that exhibited insulin resistance comparable to human Type 2 diabetes were used. The general reasoning is that if insulin is available and if ways can be found to provide ample well-functioning insulin receptors in cells, then another route to diabetes therapy is available. This avenue of research already has impacted on traditional therapy and will continue to do so as more information is gained and as more physicians become better acquainted with new techniques. The research is still in a comparatively early phase.

Some of the wide diversity of findings include: (1) Although the insulin receptor is better understood, the glucagon receptor is equally important and increasing research is being directed toward it. Where insulin in diabetics may be present in normal, higher, or lower concentrations, as determined by the type of diabetes, it has been established that glucagon is always present in greater than expected levels.

(2) Investigators have found that there are reduced numbers of insulin receptors in insulin-resistant tissues from rodents and humans. One investigator has observed that obese mice bind only 35% as much insulin as do lean mice. Other researchers have found that monocytes from Type 2 diabetics bind only about 50% as much insulin as monocytes from healthy persons — further, that there are only about 1200 receptors per monocyte from diabetics as compared with 2200 per monocyte from healthy persons.

(3) Some researchers have observed a marked inverse correlation between insulin concentration in the circulating blood and the number of insulin receptors — that is, the greater the insulin concentration in the blood, the fewer the insulin receptors in liver, fat, muscle and blood cells.

(4). Some investigators have found that the level of circulating insulin is increased by a diet high in carbohydrates, but is not accompanied by a reduction in receptor numbers. This condition holds only for an immediate time span after meals — the basal concentration of the carbohydrate-fed mice ultimately returns to a below-normal level.

(5) Researchers have found that large adipocytes from obese rats have about the same number of receptors as smaller adipocytes from lean rats; they also report no difference in glucose transport between the two types of cells, this suggesting no defect in insulin binding in the larger adipocytes. Other researchers do not agree, finding a decrease in number of insulin receptors in large adipocytes. They believe insulin binding is a membrane phenomenon and thus the most important characteristic is the number of receptors per unit area.

(6) Mathematical models of cellular membrane have been constructed, from which it has been suggested that a membrane protein, called an *effector*, must interact before the signal for insulin binding can be transmitted inside the cell.

(7) There is some indication that the increased concentration of circulating insulin may be the cause and the reduced number of receptors the effect. It has been suggested that insulin may directly catalyze the breakdown of insulin receptors. Other researchers observe that the proteolytic activity of insulin is too weak to account for the observed decrease in insulin receptors and thus the effect must be due to a poorly understood complex regulatory mechanism.

And thus the research continues. There is some consensus on a few points. A major cause of continuing diabetes in Type 2 diabetics is overeating. It is estimated that 80% of such diabetics now being treated are obese. Physicians may stress this more vigorously in the future as the disenchantment with the use of drugs and insulin for diabetic control increases. This ties in with the findings that a principal cause of the disorder is a defect in insulin binding to receptors on the cell surface. There is also growing evidence that exercise can increase insulin sensitivity and insulin cell receptors in healthy subjects and that this finding probably can be transferred to Type 2 diabetes therapy. In tests at Yale University School of Medicine (1979), six healthy men were tested. It was found that exercise did not increase insulin levels, but it did increase insulin sensitivity by 30% and the number of insulin receptors by 50%.

Insulin, as the central hormone of metabolic regulation, produces numerous diverse reactions in body chemistry in addition to its role in diabetes mellitus. These include obesity, ovarian hyperandrogenism, possibly a component of hypertension, pseudoacromegaly, leprechaunism, and lipodystrophy. As pointed out in 1991 in an excellent review article, Moller and Flier (reference listed), the glucoregulatory effects of insulin occur mainly in three body tissues — the liver, muscle, and fat. Possibly, insulin resistance could be defined more precisely as "a subnormal biologic response to a given concentration of insulin." For example, some diabetics may continue to experience hyperglycemia even when insulin dosage is high. In concluding the aforementioned article, the authors state, "Progress in understanding the syndromes of severe insulin resistance has been marked. Given the current evidence that hyperinsulinemia and insulin resistance have an important role not only in diabetes, but also in hypertension, dyslipidemia and cardiovascular disease, the molecular basis for mild insulin resistance in these disorders will merit intensive investigation in the years to come."

Yoshimasa et al. (University of Chicago and Kyoto University) described the insulin receptor as a heterotetrameric integral membrane protein composed of two alpha and two beta subunits. The alpha subunit contains the insulin binding site and is disulfide-bonded to the NH_2-terminal portion of the beta subunit.

Insulin Delivery

Over the years, much consideration has been given to insulin delivery and to blood and urine testing. The insulin delivery system is important for several reasons. The regulation of insulin secretion in human beings is complex. In nondiabetics, insulin is released by the pancreas into tributaries of the hepatic portal vein, resulting in direct delivery of insulin to the liver, the principal organ of glucose production. The close anatomic relation between the pancreas and the liver has other important effects. The liver removes about 50% of the insulin presented to it, reducing

[2] As early as 1949, researchers at the University of Pennsylvania conducted direct studies of the insulin-receptor interaction by using radioactively labeled insulin.

the exposure of the peripheral tissues to hyperinsulinemia. Insulin is an anabolic hormone that enhances storage of many important nutriments, including protein, fat, and carbohydrates — a process in which the liver has an important regulatory role. Most importantly, the sensitivity of the liver to a given concentration of insulin is much greater than that of the peripheral tissues. Thus low levels of insulin in the hepatic portal vein can regulate gluconeogenesis and glycogenolysis without inducing hypoglycemia.

Implantable insulin-delivery pumps that can safely deliver insulin intravenously or intraperitoneally have been under development for a number of years, and many have been tested and some may be in use. Most of these pumps have a fixed rate of infusion, but variable-rate pumps that would be part of a closed-loop control system could be even more effective. Whether these developments will become commonly accepted by the medical profession is still debatable.

Studies have shown that nasal delivery of insulin results in rapid peaks of circulating insulin that can control meal-induced hyperglycemia. This rapid onset of insulin action is claimed to simulate the release of insulin by the normal pancreas, at least in timing.

Attention has been given recently to methods that involve the surface of the skin as contrasted with oral, needle injection, pumps, and so on. The principle involved is termed *iontophoresis* and involves the use of tiny electric currents to drive ions across membranes. In developing the process, R.H. Guy (Univ. of California, San Francisco) learned that, in addition to substances entering into the skin, some products are exited from the skin, thus conveying the concept that perhaps iontophoresis can be used as a sampling technique as well. The technique is in a very early stage of development.

Urine testing for sugar was for many years the traditional means for determining glucose. Clinical blood testing has been widely used for many years. Kits are available for direct use by the diabetic patient.

Today, most people who take insulin to manage diabetes inject the insulin with a needle and syringe that delivers insulin just under the skin. Several other devices for taking insulin are available, and new approaches are under development.

Insulin pens can be helpful if you want the convenience of carrying insulin with you in a discreet way. An insulin pen is a device that looks like a pen with a cartridge. Some pens use replaceable cartridges of insulin; other pen models are totally disposable. A fine, short needle, similar to the needle on an insulin syringe, is on the tip of the pen. Users turn a dial to select the desired dose of insulin and press a plunger on the end to deliver the insulin just under the skin.

Insulin jet injectors send a fine spray of insulin through the skin by a high-pressure air mechanism instead of needles.

External insulin pumps connect to narrow, flexible plastic tubing that ends with a needle inserted just under the skin near the abdomen. The insulin pump is about the size of a deck of cards, weighs about 3 ounces (85 grams), and can be worn on a belt or in a pocket. Users set the pump to give a steady trickle or "basal" amount of insulin continuously throughout the day. Most pumps today have the option for setting several basal rates. Pumps release "bolus" doses of insulin (several units at a time) at meals and at times when blood sugar is too high based on the users' programming. Frequent blood glucose monitoring is essential to determine insulin dosages and to ensure that insulin is delivered.

Approaches Under Development

Implantable insulin pumps are surgically implanted, usually on the left side of the abdomen. The pump is disk shaped and weighs about 6 to 8 ounces (170 to 227 grams). It delivers a basal dose of insulin continuously. Users deliver bolus insulin doses with a remote control unit that prompts the pump to give the specified amount of insulin.

An advantage of this method is that, like insulin produced naturally from the pancreas, the insulin from the pump goes directly to the liver to prevent excess sugar production there.

The insulin patch, placed on the skin, gives a continuous low dose of insulin. To adjust insulin doses before meals, users can pull off a tab on the patch to release insulin. The problem with the patch is that insulin does not get through the skin easily.

The inhaled insulin delivery system, provides insulin as a dry powder inhaled through the mouth directly into the lungs where it passes into the bloodstream. This aerosol delivery system is about the size of a flashlight and uses rapid-acting insulin.

Pancreatic Transplantation

Pancreatic transplantation was first performed in 1966, very few procedures were performed until 1978 when new surgical techniques and improved immunosuppressive regimens increased rates of graft and patient survival. The number of procedures has continued to increase over the years. Most pancreatic transplantations in people who have diabetes with renal failure are performed at the same time as or after kidney transplantation. Only, in unusual circumstances is the pancreas transplanted alone. The survival of pancreas grafts when transplanted alone is lower than when transplanted simultaneously with a kidney.

Most pancreatic grafts are from cadaver donors. Sometimes a segment of pancreas is donated by a living related donor who is willing to undergo a hemipancreatectomy. Most pancreatic transplants are performed with quadruple immunosuppression with antibody induction therapy. Maintenance immunosuppression is triple therapy. Rejection can occur within days or after years of successful transplantation. Successful pancreatic transplantation reestablishes endogenous insulin secretion response to normal feedback regulation. However, successful pancreatic transplantation is only partially successful in reversing the renal and neural complications of diabetes. The benefits of successful pancreas transplantation seem to outweigh the risks. Although islet transplantation is less invasive than pancreas transplantation, this procedure also requires lifelong immunosuppression with drugs. In addition, transplantation of islet allografts usually fails. However, islet autograft transplantation has been successful in people without diabetes who have chronic painful pancreatitis. Development of more effective and less toxic immunosuppressive drugs may improve the success rate of islet transplantation.

Scientists have made advances in islet transplantation over the past 25 years but still face several barriers before this approach can be regarded as a real cure for diabetes. Currently, researchers are working on ways to

- obtain an adequate number of viable islets to transplant and
- prevent rejection of the transplanted islets by the body's immune system.

Islets are clusters of cells in the pancreas that produce insulin and other hormones. In type 1 diabetes, these insulin-producing cells are destroyed by the body's own immune system in an autoimmune process that scientists are working hard to understand. Researchers believe that transplanting islets is a promising experimental approach that has the potential for curing type 1 diabetes.

Obtaining enough viable islets. Studies have shown that about 1 million functioning islets must be transplanted to produce enough insulin to replace the need for injections. The number of people who could benefit from transplants is larger than the number of living organ donors, so researchers around the world are exploring potential sources of islets from deceased organ donors, from animals such as pigs, and by producing cells through bioengineering.

Preventing rejection. Rejection is the biggest problem with any transplant. The immune system is programmed to destroy bacteria, viruses, and tissue it recognizes as "foreign," including transplanted islets.

Large doses of immunosuppressive drugs are necessary to stop the immune system from rejecting the transplant. For many people with diabetes, the risks of taking immunosuppressive drugs outweigh the benefits of islet transplantation. (However, people with diabetes who must take these medications because of kidney transplants for end-stage renal disease can benefit from simultaneous pancreas transplant.)

Researchers are trying to develop methods of transplanting islets to reduce or eliminate the need for immunosuppression and the risk of rejection. Immunoisolation methods separate the islets from the immune system of the patient by coating cells or encapsulating them into microscopic containers. Immunoalteration tries to change the surface of islet cells so that the patient's immune system does not notice or attack them.

As pointed out in a 1990 paper, Kendall, et al. (University of Minnesota), observe, "Complete glycemic control is not possible in patients with diabetes mellitus who are treated with conventional therapeutic regimens. Consequently, the potential therapeutic effects of the transplantation of pancreatic islets, segments of pancreas, and the entire pancreas continue to attract attention. All reported instances of the transplantation of islets in humans have failed to result in adequate glycemic control. In contrast, the successful transplantation of segments of the pancreas or the entire pancreas result in the long-term normalization of circulating glucose levels. In the centers with the most extensive experience in

such transplantation procedures, the one-year survival rates of functioning pancreatic grafts range from 50 to 80 percent, and the patient survival rates are approximately 95 percent."

In terms of donors, hemipancreatectomy in healthy donors does result in a deterioration in insulin secretion and glucose tolerance for about 1 year after surgery. One study has shown that no further deterioration occurred from 1 to 6 years later. However, studies to date do not ensure that diabetes mellitus may or may not develop eventually in donors.

Sullivan et al. (BioHybrid Technologies, Inc.), reported in mid-1991 on the tests of a *biohybrid* pancreas. For this research, islets were prepared from adult mongrel dogs or bovine calves (less than 2 weeks old). After complex processing, the purity of the isolated islets exceeded 90–95 percent. The islets then were seeded into a specially designed device for in vivo implantation. The researchers reasoned that the ability to function in vitro perfusion culture possibly could function well as an in vivo implant. In vivo function of the biohybrid artificial pancreas was studied, using pancreatectomized dogs (an established large-animal model for diabetes research). Ten animals were selected for the study. Good control of fasting glucose levels in six of the animals was obtained — that is, without further exogenous insulin for periods up to 5 months. The researchers concluded their paper by stating, "Clearly, the ultimate therapy for diabetes should provide glycemic regulation similar to that normally provided by pancreatic islets. The study data suggest that, with improvements in device design, the biohybrid artificial pancreas should approach this goal. In addition, this same technology could lead to the development of other biohybrid organs for treatment of human diseases."

Challenging Implant Rejection. In the fall of 1990, a research team (Hospital of the University of Pennsylvania) led by Ali Naji reported on what could be a breakthrough in pancreatic transplantation and possibly, in the long term, could offer a cure for diabetes!

Past pancreatic transplantations have involved isolated pancreatic islets and, in some cases, human islet allografts. Even with the administration of immunosuppressants, the body rejects them. The islets are more vulnerable to rejection than are vascularized organ allografts, such as kidney, liver, or whole pancreas (see Kennedy reference listed). Greater success has been achieved in experimental animals than in human recipients.

The Naji research group has taken advantage of what may be termed *immunologically privileged sites* — in this case, the thymus. T lymphocytes mature in the thymus. As described under **Immune System and Immunology**, T cells are "taught" in the thymus to respond to a particular antigen. Thus, transplantation of "foreign" substances here may have some special significance in terms of bypassing rejection.

For the Naji research team, the concept appears to have worked in the case of rats that develop autoimmune diabetes. The next step will be trials with larger animals, such as dogs. The concept is challenging and different and could be widely encompassing. As Naji states, "Way down the road you might be able to implant a bit of heart or liver tissue in the thymus to modify the immune system, and then later implant the entire organ without the need for immunosuppressants."

Exercise as a Factor in Diabetes Mellitus

Although the precise relationships between exercise and non-insulin-dependent diabetes mellitus remain poorly understood, it is widely accepted among professionals that exercise increases insulin sensitivity, whereas deconditioning and physical inactivity both are associated with the development of insulin resistance. However, it has been found that brief, intermittent exercise has no long-term positive effects. The general hypothesis is that the number and activity of glucose-transporter proteins are increased in plasma membranes of skeletal muscle after exercise (Goodyear et al. 1990). Further, glycogen synthase activity is increased, resulting in increased synthesis of glycogen and increased nonoxidative disposal of glucose. During exercise programs, the binding of insulin to its receptors is slightly increased in adipose tissue, but not in muscle.

E.S. Horton (Univ. of Vermont), in an excellent review of exercise and decreased risk in NIDDM, concludes: "Regular physical activity is an important complement of a healthy lifestyle for all of us, but it may be particularly important for those at increased risk for chronic diseases, such as NIDDM, hypertension and hyperlipidemia."

Platelet Activity in Diabetes Mellitus

For some years, it has been suggested that platelet hyperreactivity in patients with diabetes mellitus is associated with increased platelet production of thromboxane. Reported in 1990 were the results of a study conducted by Giovann, et al. (Univ. Chieti, Palermo and Rome, Italy), of 50 patients with Type 2 diabetes who had normal renal function and clinical evidence of macrovascular disease and in 32 healthy controls. The study demonstrated that tight metabolic control can affect the actual rate of thromboxane formation in vivo, but it did not clarify the mechanism or mechanisms responsible for the effect. Changes in plasma glucose or insulin levels, reduced nonenzymatic glycosylation of collagen, reduced plasma protein B levels, and changes in the properties of red-cell and platelet membranes have all been proposed as factors contributing to altered platelet reactivity in diabetes mellitus.

Genetic Factors

Pyke and associates (King's College Hospital, London) studied 100 pairs of identical twins in genetic research on diabetes mellitus in the early 1970s. Although twins had been studied earlier by other investigators, this was by a substantial margin the largest sample ever undertaken. Among the conclusions drawn was that genetic factors are predominant in Type 2 diabetes, but that factors, such as virus infection, environmental substances, etc., are required to trigger the disease in a genetically diabetes-prone individual. Conclusions have since been modified. In recent years, considerable attention has been given to determining the relationship between diabetes and the histocompatibility antigens. These antigens are sometimes referred to as the HLA system. In research at the Steno Memorial Hospital (Copenhagen, Denmark), it was found that two HLA systems (B8 and B15) were found in diabetics with an occurrence three times that of nondiabetics — but that this rate applied only to Type 1 diabetes and not Type 2. It was also found that with HLA antigens at the D locus (with more than one high-risk allele present in the same person), the chance of developing Type 1 diabetes was increased up to ten times. Later research showed that certain HLA alleles are associated with a decline in the incidence of Type 1 diabetes. As pointed out by Notkins (1979), "... the high-risk alleles associated with the HLA complex might code for a deficient immune response to agents that preferentially attack beta cells, thereby allowing beta-cell damage and diabetes to result. Conversely, the protective alleles might enhance the host's immune response to such invaders."

Thus, although differing, genetic correlations have been found in both Type 1 and Type 2 diabetes. Considerably more research is required to transform genetic findings into methods of prevention and therapy.

Drug-Induced Diabetes Mellitus

The association between drugs (as causative factors) and diabetes mellitus has not been researched extensively. It is true that the drug *alloxan* has been known since the 1940s to be capable of destroying beta cells and of inducing diabetes in laboratory animals. Highly selective damage to beta cells can be noted within a few minutes after injection. It was also found in the early 1960s that the drug *streptozotocin* is toxic to beta cells and similarly induces diabetes in laboratory animals. In more recent research, workers at the University of Massachusetts Medical School have shown that controlled multiple doses of the drug can alter beta cells so that they become vulnerable to attack by the animal's immune system. This line of experimentation has also shown that genetic factors are an important factor in susceptibility to the drug.

In 1975, a rodent poison with a molecular structure similar to that of streptozoticin was put on the market in the United States. Accidental injection of the drug caused acute diabetes (requiring insulin therapy) in at least 20 survivors to the exposure. At autopsy, two of the fatalities from such poisoning showed beta cell destruction. A few other drugs and chemicals have been shown to be toxic to beta cells.

Search for a Viral Connection

The possible implication of virus infection as a primary cause or triggering event that leads to diabetes mellitus dates back to the early 1900s when a physician in Philadelphia noted that diabetes shortly followed mumps in one of his patients. Over the years, there have been a number of similar reports possibly associating the onset of diabetes closely following an infection (particularly of mumps), but no convincing string of evidence was

developed. In fact, some authorities pointed out that if such a connection exists, considering the incidence of mumps and the incidence of diabetes mellitus without such a connection, the combination of circumstances indeed must be rare — and it was further suggested that to support the connection, a special and rare strain of mumps virus must be assumed, or that a relatively few people may have some unusual, possibly genetically determined, response to mumps virus. Researchers in Australia also pointed to a possible connection between rubella (German measles) and diabetes. A more convincing tie between viruses and diabetes came out of research commenced in 1968 at the University of Vermont College of Medicine, where a connection between a variant of encephalomyocarditis (EMC) virus and diabetes in laboratory mice was demonstrated. Examination of the pancreas of infected animals showed damaged beta cells as well as inflammatory white cells in the islets of Langerhans. However, proof that the damage was caused by the virus was not fully developed. In following this avenue of research further, researchers at the National Institutes of Health have more recently demonstrated, through the use of immunofluorescence micrography, that EMC can infect and damage beta cells, primarily by replication of the virus within the cells. Further research has indicated that upon cell damage there is an abnormal release of insulin into the circulation, thus lowering the blood glucose level, but that within a few days the animal's reserve of insulin is depleted to a subnormal level. The animals then demonstrate the symptoms (consumption of excessive amounts of water and food) of Type 1 diabetes.

Generalities pertaining to a virus-diabetes connection could not be made at this juncture, however, because it was found that only certain inbred strains of mice developed the disease. After many breeding experiments (crossing and backcrossing), it was concluded that a single gene locus appears to play a major role in determining susceptibility to this particular EMC-induced diabetes. Subsequent research has indicated that the susceptibility to the virus may be a function of the number or type of viral receptors on the surface of the beta cells. During the 1970s, a number of other viruses were tested for a possible diabetes connection, including Coxsackie virus and respiratory-entero-orphan virus, among others. See also **Coxsackie Virus**.

The first direct evidence of a connection between a virus infection of a human and diabetes was reported by Notkins and associates (National Institute of Dental Research, National Institutes of Health, and National Naval Medical Center) in 1978. The researchers succeeded for the first time in isolating virus Coxsackie B4 from the pancreas of a 10-year-old boy who had developed a fatal case of diabetes soon after a flu infection. When the same virus was injected into laboratory animals, certain inbred mice developed the same disabling type of diabetes. These findings also strengthened the theory that inherited susceptibility may play a key role, since only certain inbred laboratory animals developed the disease in the course of the experiments.

It is postulated by a number of authorities that viruses may be only one of several fundamental causes of diabetes mellitus and, in fact, may be a minor cause. It is further postulated at this juncture that several and even many viruses may be involved in this connection and, if so, the outlook for a vaccine to prevent diabetes does not appear good in the near future, the situation being somewhat similar to that of the common cold that has numerous causative agents.

Protein Glycosylation

Protein glycosylation is important in the maintenance of the integrity of plasma membranes and in facilitating the secretion of proteins into the extracellular space. These modifications are usually precisely controlled by enzymes. In contrast, certain proteins may undergo nonenzymatic glycosylation. This appears to be the case with human hemoglobin. Much has been learned concerning the structure and biosynthesis of glycosylated hemoglobins in recent years, including data that have a bearing on certain areas in diabetes research. This includes a more accurate measurement of glucose intolerance, particularly in borderline cases. The new findings are also relevant to studies of the complications of diabetes mellitus. The aforementioned researchers have observed that the organs and tissues most affected by diabetic complications (lens, peripheral nerves, kidney, retina, blood vessels) are not insulin-dependent for glucose penetration and thus achieve high intracellular glucose concentrations during periods of hyperglycemia. These intracellular glucose levels have been shown as causative factors for the formation of some diabetic complications. A particular hemoglobin (A_{1c}), found in higher concentration in some diabetics, may serve as a useful model of nonenzymatic glycosylation of other proteins that may be involved in the long-term complications of diabetes.

DIABETIC RETINOPATHY. Diabetes can attack the eyes in several ways. For example, it increases the risk of glaucoma and cataracts. But primarily it affects the retina, the light-sensitive membrane at the back of the eye, causing a variety of problems that are collectively called diabetic retinopathy.

The disease occurs most frequently in Type I, or early-onset, diabetes, in which the insulin-making cells of the pancreas are destroyed so that regular infusions of insulin are needed. However, it also occurs in more common Type II, or noninsulin-dependent, diabetes, in which the body's production or use of insulin declines with age.

Diabetes causes deterioration of the small blood vessels of the eye, specifically, in the cells that line the interior of those blood vessels, the basement membrane, the endothelial cells that lie above them, and the pericytes, which are supporting cells. The basement membrane becomes thicker and the number of pericytes decreases, so the blood vessels begin to leak.

This results in a condition called nonproliferative diabetic retinopathy. One effect of the disease is formation of microaneurysms; bulges that can leak fluid into the retina. This leakage can cause macular edema, the most common cause of diabetic visual impairment. In this disease, the extremely sensitive central area of the retina, the macula, deteriorates. Central vision becomes worse, so reading and other functions are impaired.

Macular edema can be treated by a relatively new technique called photocoagulation, in which argon laser light is used to weld the leaking blood vessels. The light can be beamed at specific small vessels or, if leakage is widespread, at a large number of vessels. Laser treatment can stop the deterioration, but it cannot restore vision loss, so earl detection is essential.

Other kinds of damage caused by nonproliferative diabetic retinopathy include:

Dot hemorrhages—very small areas of bleeding.

Blot hemorrhages—larger areas of bleeding.

Cotton wool spots—blockage of tiny retinal blood vessels.

Another form of diabetic eye damage is proliferative diabetic retinopathy, an overgrowth of new blood vessels in the retina. This overgrowth generally happens years after diabetes has been diagnosed.

Although the reason for the proliferation of these retinal blood vessels is unknown, it is believed to be the body's response to the damage that diabetes causes to existing blood vessels. The new blood vessels are abnormally flimsy, and their growth is not under normal controls, so they leak blood and can grow through the retina into the vitreous gel that fills the eye.

The vessels are so leaky that even normal head movements, such as a sneeze or the rapid eye movement (REM) that occurs during sleep, can cause them to break and hemorrhage. The resulting hemorrhages can send blood into the retina, the area between the retina and the vitreous gel, or the vitreous. The result can be a blind spot in part of the visual field or spots and cobwebs that progressively impair vision. In the worst-case scenario, vitreous hemorrhage can cause blindness.

The body does respond to these hemorrhages, with a natural cleaning effort to remove the blood from the retina or vitreous. But this response can also cause damage, by producing scar tissue. Sometimes scar tissue can break away, attaching itself to other parts of the retina or optic disc. Or scar tissue can contract, causing a retinal detachment. In the worst case, a retinal detachment in the macula causes permanent, severe vision loss.

Proliferative diabetic retinopathy can also be helped by laser treatment. This treatment usually requires many more bursts of laser light than used for the nonproliferative form of diabetic retinopathy. Up to 2,000 bursts may be needed, in two or three sessions. This laser treatment causes the formation of artificial scars, which help prevent severe loss of vision in many patients.

Vitreous hemorrhage can be treated by a technique called vitrectomy, which uses specially designed instruments to remove the area of hemorrhage. Laser therapy or cryotherapy, using extreme cold, can be applied during vitrectomy to improve the effectiveness of the treatment. As with any complication of diabetes, the best treatment is prevention. Many studies have shown that effective control of blood sugar levels, by insulin therapy in Type I diabetes and by dietary measures and medications in Type II diabetes, delays the onset and slows the progression of retinopathy. Controlling blood pressure and weight, and treating infections promptly also reduce eye problems and other diabetic complications. Regular eye examinations are recommended for all diabetics.

The American Academy of Ophthalmology recommends the following schedule of eye examinations for diabetics:

- *For persons who contract diabetes before reaching age 30* a first eye examination five years after diagnosis, with annual exams hereafter and more often if symptoms of trouble develop.
- *When diabetes is diagnosed when a person is more than 30 years old* an eye examination as soon as the diagnosis is made, with annual eye examinations thereafter.

Pregnancy is a special case. An examination is recommended before conception for diabetic women who are attempting to become pregnant, and early in the first trimester when pregnancy occurs, with a follow-up examination three months later.

Vision Rx, Inc., Elmsford, NY

DIAGENESIS. A term proposed by Gumbel in 1888 for the gradual and successive chemical–physical changes that take place in sediments previous to or during their consolidation. Diagenesis may also include the numerous processes of lithification but is a useful term only when particularly applied to the more or less contemporaneous chemical alteration of sediments.

DIAGNOSTICS (Computer System). Programs provided to the maintenance engineer or operator to assist in discovering the source of a particular computer system malfunction. Diagnostics generally consist of programs that force extreme conditions (the worst patterns) on the suspected unit with the expectation of exaggerating the symptoms sufficiently for the engineer to readily discriminate between possible faults and to identify the particular fault. In addition, diagnostics may provide assistance in localizing the cause of malfunction to a particular card or component in the system.

There are two basic types of diagnostic programs: (1) on-line; and (2) off-line. Off-line diagnostic programs are those that require that there be no other program active in the computer system, sometimes requiring that there be no executive program in the system. Off-line diagnostics are typically used for central processing unit (CPU) malfunctions, very obscure and persistent peripheral device errors, or for critically time-dependent testing. For example, it may be suspected or known that a harmonic frequency is contributing to the malfunction. Thus, it may be desirable to drive the unit continuously at various precise frequencies close to the suspected frequency to confirm the diagnosis and then to confirm the cure. Interference from other activities may well make such a test meaningless. Thus, all other activity on the system must cease.

On-line diagnostics are used mainly in multiprogramming environment and are vital to the success of real-time systems. The basic concept is that of logically isolating the malfunctioning unit from all problem programs and allowing the diagnostic program to perform any and all functions on the unit. Many of the more common malfunctions can be isolated by such diagnostics, but there are limitations imposed by the interference from other programs that also are using the CPU.

Diagnostic procedures, often automated, also apply to other forms of industrial and business equipment. See Alphabetical Index.

DIAGONAL (Structural). Any inclined web member of a truss other than the end post is known as a diagonal. Under various live load conditions, certain web members of a bridge truss may be subjected to a reversal of stress. Stiff diagonals are web members designed to carry either tension or compression. Tension diagonals are assumed to be incapable of resisting any appreciable amount of compression.

When the diagonals are designed to take tension only (are not stiff) two are required, sloping in opposite directions, in a panel where either one, acting alone, would have its stress reversed. When one of these diagonals is acting the other is out of action for all practical purposes. The one that carries the dead load stress when no other loads are on the bridge is called the main diagonal. The other which comes into play when the main diagonal goes out of action is the counter. See also **Beam (Structural)**.

DIALLAGE. The mineral term for a calcium-iron pyroxene, similar in chemical composition to diopside but richer in iron oxide. In addition to the typical prismatic cleavage of the pyroxene group diallage has a marked "cleavage" parallel to the vertical pinacoids, known as diallage parting. Diallage is a common constituent of gabbros. The term diallagite was proposed by Cloiseaux in 1845 for rocks particularly rich in diallage. The term diallage is derived from the Greek meaning difference, and referring to the peculiar cleavages of this variety of monoclinic pyroxene. See also **Pyroxene**.

DIALYSIS. The process of separating compounds or materials by the difference in their rates of diffusion through a colloidal semipermeable membrane. Thus, sodium chloride diffuses eleven times as fast as tannin and twenty-one times as fast as albumin. When the process is conducted under the influence of a difference in electrical potential, as from electrodes on opposite sides of the semipermeable membrane, it is called electrodialysis.

An apparatus for carrying out a dialysis usually consists of two chambers separated by a semipermeable membrane of parchment paper latex, animal tissue, or other colloid. In one chamber the solution is placed, and in the other, the pure solvent. Crystalline substances diffuse from the solution through the membrane and into the solvent much more rapidly than amorphous substances, colloids or large molecules.

The use of dialysis in connection with the treatment of kidney diseases is discussed under **Kidney and Urinary Tract**.

DIAMAGNETISM. Diamagnetism is the phenomenon in which the magnetization in a substance opposes the magnetizing force that induces it. Diamagnetism is considered to exist in all substances, although in substances exhibiting paramagnetism or ferromagnetism, it is masked by the much greater opposite effect due to the orientation of the magnetic atoms or molecules.

DIAMOND. An allotropic form of carbon, diamond over the centuries has been known best for its use by the jewelry trade as a precious stone. See also **Gem Stones**. See Fig. 1. Although diamond possesses several outstanding properties as a material, its hardness largely has accounted for the industrial uses of diamond for cutting and polishing operations. Until comparatively recently, industrial diamonds were the byproducts of gem stone-mining operations. Although numerous researchers over the years have been attracted by the possibility of creating diamonds synthetically, only during the last decade or two has sufficient progress been made in diamond synthesis to forecast the production of industrial diamonds in tonnage quantities at affordable prices. In addition to the traditional use of diamond because of its hardness, other properties of this outstanding material (heat conductivity, for example) are exploited. Annual industrial diamond production, which amounted to about $200 million in 1991 is expected to exceed $1 billion by the end of the century. As of 1994, research is continuing at an aggressive pace, notably in Japan; a few firms in the United States also are quite active in the field. Over the years, Russian scientists also have been developing a position in synthetic diamond technology.

Important Properties of Diamond. Diamond has the highest atom-number density of any known material at terrestrial pressures.[1] Because of its high atom-number density and strong covalent bonding, diamond has the highest hardness and elastic modulus of any material and is the least compressible substance known. The thermal conductivity of diamond at 300 K is higher than that of any other material, and its thermal expansion coefficient at 300 K is 0.8×10^{-6}, lower than that of *Invar* (an Fe-Ni alloy). Diamond is a very wide-band gap semiconductor ($Eg = 5.5$ eV), has a high breakdown voltage (10^7 V cm^{-1}), and its saturation velocity of 2.7×10^7 cm s^{-1} is considerably greater than that of silicon, gallium arsenide, or indium phosphide.

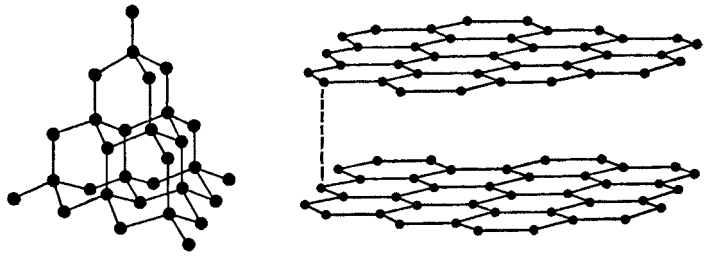

Fig. 1. A gross conceptualization of the space lattices of (**a**) diamond, and (**b**) graphite. See new spatial concept for graphite in article on **Carbon**. Diamond crystallizes in the cubic system, is the hardest of known substances (10 on the Mohs scale; 5,500–7,000 on the Knoop scale), specific gravity 3.51–3.521 (20 °C), dielectric constant at 10^4 Hz, 16.5, at 10^8 Hz, 5.5, index of refraction 2.417–2.4195. Classically, a diamond crystal may be pictured as a huge polymeric molecule, very tightly packed, with a density about 1.6 times greater than the other allotropic form of carbon, graphite. The normal C–C single bond distances in the atomic lattice of diamond are all 1.54 Å, whereas in graphite the C–C bond distances are 1.42 Å. The tight packing of diamond accounts, of course, for its relatively high density and for its extreme hardness. Graphite, on the other hand, essentially is comprised of two-dimensional molecules, very laminar, and which tend to slide and thus impart lubricity to the substance.

Because of these several outstanding qualities, as early as 1988, J.C. Angus and C.C. Hayman (Case Western Reserve University) observed, "There is great interest in using single-crystal diamond for heat sinks and as an active semiconductor element. Potential electronic applications of diamond include high-temperature devices, millimeter-wave traveling wave amplifiers, backward-wave oscillators, and picosecond high-voltage electro-optic switches. Some potential applications may require only polycrystalline films, for example, laser and x-ray windows, lenses, bearing surfaces, and tribological coatings." Several of these applications already have been demonstrated as of the mid 1990s.

Naturally Occurring Diamonds

Geologists observe that probably all of the known diamonds found prior to 1725 had been found in India. In that year, diamonds were discovered in Brazil, a source that has continued to present times. Most Brazilian stones, however, are comparatively small.

Diamonds were discovered in 1867 along the Orange River in South Africa, and since then Africa has been preeminent in the production of diamonds; in the seventies and eighties occurred a series of amazing discoveries of diamond fields and stones of extraordinary size. Diamonds have also been found in Australia, Borneo, British Guiana, and Arkansas.

Much as the matter has been studied there is no consensus as to the genesis of the diamond. It is found in alluvial deposits, both unconsolidated and consolidated, indicating the erosion of rocks containing diamonds not only during the present era but also in past geologic time. In Africa diamonds are mined in a dark basic rock of the general nature of peridotite called kimberlite from the town of Kimberley. The kimberlite occurs in vertical "pipes," resembling what once may have been volcanic necks or other types of igneous rock conduits. It is supposed that the diamonds have been formed in and brought to the surface by the magma, which was of the general nature of peridotite. Undoubtedly high pressures, and possibly high temperatures as well, are necessary for the development of crystallized carbon in the form of diamonds.

Expanded insight concerning the formation and occurrence of diamonds in southern Africa is provided by Boyd (Carnegie Institution of Washington) and Gurney (University of Cape Town) in a paper dealing with diamonds and the African lithosphere. In addition to gaining a better understanding of diamonds, the researchers point out that new knowledge on the

[1] Diamond possibly may be exceeded by the superdense carbon reported by Matyusenko, et al., 1979. (See reference listed.)

structure and history of the Kaapvall craton in which diamonds occur has been gained. See also **Craton**. As pointed out by the investigators, high pressures are required for the crystallization of diamonds, corresponding to depths in the earth's mantle of at least 150 kilometers. Diamonds formed at those depths have been brought to the surface in volcanic eruptions of kimberlite. See also **Kimberlite**. Diamonds are found in minute concentrations (+ ppm) in kimberlite that has filled the throats of ancient volcanoes, such as those at Kimberley, where igneous occurrences of diamonds were first recognized. Erosion of kimberlite pipes and transport of diamonds in streams and rivers has dispersed them beyond the boundaries of the craton, in some cases forming secondary concentrations in stream gravels and beach deposits.

In a summary of their findings, Boyd and Gurney state that the Kaapvall craton has a root composed in large part of peridotites that are strongly depleted in basaltic components. See also **Peridotite**. The asthenosphere boundary shelves from depths of 170 to 190 kilometers beneath the craton to approximately 140 kilometers beneath the mobile belts which border the craton on the south and west. The root formed earlier than 3 billion years ago, and at that time ambient temperatures in it were 900 to 1200 °C. These temperatures are near those estimated from data for xenoliths erupted in the Late Cretaceous or from present-day heat-flow measurements. Many of the diamonds in southern Africa are believed to have crystallized in this root in Archean time and were xenocrysts in the kimberlites that brought them to the surface. Information about the composition and history of this root is being gathered through study of mineral inclusions in diamonds. Multiple, separate inclusions in individual diamonds are abundant. Sulfides form the most abundant inclusions, but garnet, olivine, pyroxenes, and chromite are also relatively common. For the reader who is seriously interested in South African diamond resources, reference to the full Boyd — Gurney report is suggested.

The manner in which large diamonds are cut and the weight of famous large diamonds is given under **Gem Stones**. Growing interest by the jewelry trade in the so-called *pink diamond* has been demonstrated in recent years. As pointed out by P. Proddow and M. Fasel (See reference listed), "Pink diamonds became readily available only in 1984. Now they are used to surround everything from a 79-carat peridot from Burma to a starfish broach to black and white pearls in twin heart earclips."

Synthesis of Diamond

It is reasonable to assume that interest in synthesizing diamonds, driven by the scarcity of natural diamonds[2] extends back to the days of alchemy. Contemporary research involving either high-temperature, high-pressure methods or chemical vapor deposition (CVD) processes commenced in the late 1940s. Important early work was performed at Case Western Reserve University in Cleveland, Ohio and at the Institute for Physical Chemistry, Moscow, Russia. In 1949, W.G. Eversole (Union Carbide Corporation) was the first researcher to grow diamond successfully at low pressures. Conclusive proofs and repetitions of the experiments occurred in early 1953 and thus appears to predate the diamond synthesis at high pressure by investigators at General Electric Company, which was reported as accomplished in December 1954, but which was not announced publicly until 1955. Essentially contemporaneously, Liander (Allemanna Svenska Elektriska Aktiebolaget ASEA) in Sweden reported synthesis of diamond. It is interesting to note that Eversole grew new diamond on preexisting diamond nuclei, whereas the GE and ASEA syntheses commenced with nondiamond carbons.

As reported by J.C. Angus and C.C. Hayman (Case Western Reserve University), "B. Deryagin (Russia), who started work on low-pressure diamond synthesis in 1956 has had the longest sustained research effort on metastable diamond growth of any worker." Deryagin's group initiated many approaches to the problem, starting with the growth of diamond whiskers by a metal-catalyzed vapor-liquid solid (VLS) process. Later, the group researched epitaxial growth from hydrocarbons and hydrocarbon-hydrogen mixtures, using different forms of vapor transport reactions. The Deryagin group also concentrated on theoretical investigations of the relative nucleation rates of diamond and graphite. See Fig. 2.

J.C. Angus and co-researches at Case Western Reserve University (CWRU) targeted principally the CVD process, by attempting to deposit

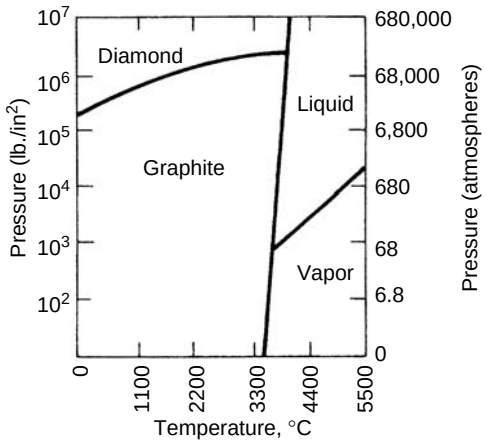

Fig. 2. Phase diagram approximation of carbon, indicating pressure-temperature parameters favoring yield of graphite and diamond. See also phase diagram in the article on **Carbon**.

diamond on diamond seed crystals from hydrocarbons and hydrocarbon-hydrogen mixtures. The CWRU team grew P-type semiconducting diamond from $CH_4-B_2H_6$ gas mixtures and studied the rate of diamond and graphite growth in CH_4-H_2 gas mixtures and ethylene. The group was the first to report on the preferential etching of graphite compared to diamond by atomic hydrogen and noted that boron had an unusual catalytic effect on metastable diamond growth. The role of hydrogen in permitting metastable diamond growth was a constant thread throughout the early work.

Numerous other groups worked on the problem, and it was demonstrated that the presence of hydrogen enhanced yields of diamond. The addition of hydrogen to the hydrocarbon gas phase was shown to suppress the growth rate of graphite more than it suppressed the growth rate of diamond, resulting in higher diamond yields. However, graphitic carbons nucleated on the surface and suppressed further diamond growth. It was necessary to remove the graphitic deposits preferentially, with atomic hydrogen or oxygen, and to repeat the sequence.

Isotopically Adjusted Diamonds. The ratio of isotopes in natural diamond is about one carbon-13 atom for every 100 atoms, the remainder being carbon-12 atoms. During the early 1970s, R. Seitz (Harvard University) became convinced, it is reported, that an isotopically pure diamond (all carbon-12 atoms) would be an excellent conductor of heat and less susceptible to damage by a laser beam. In July 1990, General Electric announced that it had made an isotopically pure carbon-12 diamond. Tests and calculations have shown that a diamond of all or nearly all carbon-12 atoms had been produced. Apparently, the methane gas used in the CVD process can be enriched with either C-12 or C-13, after which thin mosaics of tiny diamond grains serve as feedstock for a week-long process involving 1000 tons of pressure and a temperature of about 1500 °C. The operation may be described as a slow diffusion process. Because of the time factor and extreme conditions, costs are high. J.C. Angus (CWRU) suggests, "An alternative route for growing the gem-sized diamonds might develop from the vapor deposition methods now used for growing diamonds." Subsequent research by various groups has indicated that an all carbon-13 diamond may be even better than the pure carbon-12 structure. Quantum mechanical calculations have indicated that slightly more atoms cause the atoms to be about .015 percent closer. This could translate into practical end-use properties, including hardness, among other property changes still unknown. It is reported that a carbon-13 diamond had been produced in 1971, but that it had not been reported officially. Some scientists now note that in the future diamonds may become commercially available on a "ready to order," isotopic ratio basis.

John Angus (CWRU) has suggested that an alternative route for growing gem-size diamonds may develop from the vapor deposition methods now used for growing diamond films.

Diamond Films. Two principal classes of diamond film deposition have been developed: (1) PACVD (plasma-assisted chemical vapor deposition) and (2) IBED (ion-beam-enhanced deposition).

A.H. Deutchman and R.J. Partyka (Beam Alloy Corporation) observe, "Characterization and classification of thin diamond films depend both on

[2] Proof that diamond is an allotropic form of carbon was given by the English chemist, Smithson Tennant, in 1797.

advanced surface-analysis techniques capable of analyzing elemental composition and microstructure (morphology and crystallinity), and on measurement of macroscopic mechanical, electrical, optical and thermal properties. Because diamond films are very thin (1 to 2 micrometers or less) and grain and crystal sizes are very small, scanning electron microscopy and transmission electron-microscopy techniques must be used to examine film morphology. Crystallinity is measured by various techniques including x-ray and electron diffraction Auger electron spectroscopy, and laser Raman spectroscopy."

Analysis of chemical composition is important because large percentages of hydrogen can be incorporated in the films, especially with PACVD techniques. This can cause a wide variety of hydrogenated structures.

Diamond films, although not approaching bulk diamond, are harder than most refractory nitride and carbide thin films, which makes them attractive for tribological coatings. Transparency in the visible and infrared regions of the optical spectrum can be maintained and index-of-refraction values approaching that of bulk diamond have been measured. Electrical resistivities of diamond films have been produced within the full range of bulk diamond, and thermal conductivities equivalent to those of bulk diamond also have been achieved. As substrates for semiconductor electronic devices, diamond films can be produced by both the PACVD and IBED techniques.

Diamonds in Meteorites. The presence of diamond in extraterrestrial specimens first was detected in the late 1800s. Inasmuch as meteorites are believed to originate from relatively small bodies (only a few hundred km in diameter or less), the origination of meteorite diamond is believed to differ from the diamond-forming process on Earth — mainly because of the absence of high pressures as found on Earth. Researchers recently have observed, "There is considerable need to subject diamonds from Abee (enstatite chondrite) and, for that matter, diamonds from ureilites and iron meteorites to the kind of scrutiny being given to the nanometer-sized component Cδ. It may be that low-temperature, low-pressure (that is, nonshock) formation of diamond was an important process in the early inner solar system." See also **Meteoroids and Meteorites**.

DIAMOND ANVIL HIGH PRESSURE CELL. The behavior of matter under extreme pressure is of great interest to several scientific disciplines and scientists working in the field of high pressure research are continually striving to achieve higher and higher pressure, to expand our knowledge in the field. Modern high pressure research falls under two categories — *static* and *dynamic*. Static high pressure is sustained pressure acting on a sample, while dynamic pressures last only a few millionths of a second and are generated by a shock wave. While dynamic pressures in the megabar range* (millions of atmospheres) can easily be generated, static pressures of this magnitude are hard to realize. Only recently, this has become possible through the introduction of a novel pressure generating device called the *Diamond Anvil Cell* (DAC). The DAC has practically replaced all other pressure generating devices used in high pressure research and is proving to be a versatile tool to study the high pressure behavior of matter. With the DAC, pressures of 5 megabars (5 million atmospheres) have recently been achieved.

Why diamond works so well is because of its two most desirable properties, namely, (1) it is the hardest substance known to science, and (2) it is very transparent to optical radiation as well as to x-rays. Compared to diamond, tungsten carbide, which was used in older pressure generating devices, has a much lower compressive strength and, further, it is opaque to radiation.

The Diamond Anvil Cell

In Fig. 1 a modern DAC capable of generating megabar pressures is shown. Quite contrary to the general conception of high pressure apparatus, the DAC is such a compact device that it fits in the palm of a hand. Figure 2 shows the basic elements of the DAC. The arrangement shown consists of two flawless (gem quality) diamonds, one-third to one-half carat in weight. The pointed ends of the diamonds are ground off and polished to produce small flats of about 0.5 millimeter in size and are set in opposition to each other. When a metal gasket is compressed between these small flat faces very high pressure is generated in the gasket. To apply this pressure on a sample, a hole is drilled in the gasket for locating the sample and the pressure-transmitting medium. Because the area over which the force is concentrated is extremely small, the pressure on the sample, which is force per unit area, can be enormous. For the same reason a force that can be applied by hand is multiplied 500 to 1000 times by the mechanism, which makes the DAC a very compact apparatus. In a practical DAC such as the one shown in Fig. 1, the two diamonds are mounted inside a hardened steel mechanism, machined to high tolerances, that imparts thrust along an axis perpendicular to the diamond faces. For the successful operation of the DAC, the two diamond flats have to be set perfectly parallel to each other and further they should be accurately centered along the common axis. The mechanism carries hardened steel or tungsten carbide rockers for diamond support and alignment. The thrust and alignment mechanisms can be designed in different ways, and hence, several types of diamond cells have evolved.

The simple operation of the DAC is the hard-won result of two decades of evolution in design. High pressure devices employing diamonds were first built in 1959 by C.E. Weir, E.R. Lippincott, A. Van Valkenburg and E.N. Bunting of the National Bureau of Standards, and J.C. Jamieson, A.W. Lawson and N.D. Nachtrieb of the University of Chicago, independently and simultaneously. Since that time, the NBS Scientists and several other groups have developed the DAC as a fine tool for ultrahigh pressure research.

In a diamond cell, the sample volume is sacrificed for the sake of higher pressures, and hence, all operations connected with the cell have to be performed under a microscope. In preparing the DAC for an experiment, the first step is to indent the metal gasket (hardened stainless steel strip or Inconel strip) with the anvil diamonds to the correct thickness (50 to 100 micrometers) and then drill a 100- to 200-micrometer hole as close to the center of the indentation as possible. The gasket is seated on the face of one of the diamonds in the same orientation as it had when the indentation was made. The sample material and a small chip of ruby for pressure calibration are then placed in the hole. Finally, to maintain hydrostatic pressure the hole is filled with a tiny drop of fluid from a syringe and then the hole is quickly sealed by the diamond faces before the fluid evaporates.

When thrust is applied, the metal gasket is compressed, and along with it the pressure medium and the sample. Because of the greater compressibility

* Pressure is usually expressed in bars, atmospheres, or pascals. One bar = 0.9868 atmosphere = 10^5 pascals. One megabar = 10^6 bars = 100 GPa (giga pascals).

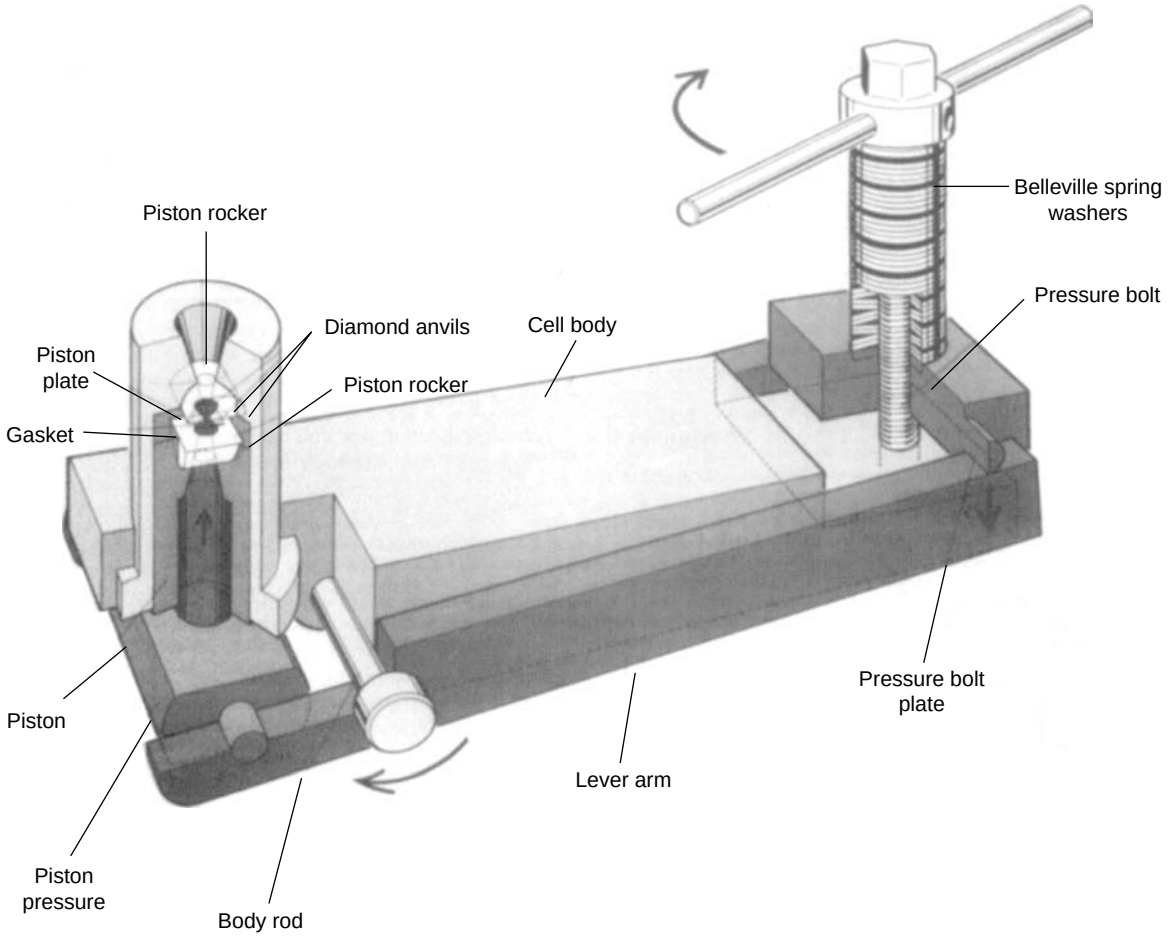

Fig. 1. Modern diamond anvil cell of the type developed at the Geophysical Laboratory of the Carnegie Institution in Washington, DC. It is about 20 cm long and weighs about 3 kg. The piston and cylinder are machined to very high tolerances. The anvil diamond on the piston is fixed on a half-cylindrical rocker mount recessed into the piston. The other anvil diamond is inside the cylinder and sits on a similar rocker mount. The two rocker mounts are set at right angles and can be moved laterally with screws to center the diamond flats. Parallel alignment of the diamond flats is accomplished by tilting the two half-cylindrical rockers until the optical interference fringe pattern appearing in between the two flats is reduced to a uniform gray color, and then locking the rockers in position with set screws. Thrust is generated by turning the handle on the spring-loaded pressure bolt clockwise. The thrust is transmitted by the long lever arms and is delivered to the movable piston as a vertical upward force through the action of the fulcrum (the rod on the side goes into the body of the cell and acts as the fulcrum) and a swiveling piston pressure plate (not seen in the figure). The lever arm mechanism magnifies the thrust and delivers it to the piston plate which, in turn, pushes the piston diamond against the stationary diamond attached to the cylinder. One of the finest features of the diamond anvil apparatus is that pressurized samples can be viewed directly with an optical microscope. (*From "The Diamond-Anvil High-Pressure Cell" by A. Jayaraman. Copyright © April 1984 by Scientific American, Inc. All rights reserved.*)

of the pressure medium, the pressure on the gasket is always greater than the pressure on the contents in the hole, and this ensures perfect sealing of the pressure chamber. The optimum hardness for the gasket is an important element in diamond cell work, for too soft a gasket would simply flow like butter, and too hard a gasket would not compress. The purpose of the gasket is to provide containment for the pressure medium as well as to give support to the diamond flats. The higher the pressure, the harder the gasket material should be.

Megabar Pressures. To reach megabar pressures, the diamond flats have to be modified to what is known as beveled geometry. This is shown in Fig. 3. In this a part of the flat has been beveled; the bevel angle is typically 5°. The flat region B and dimension A are variable, and for megabar pressures they are usually 50 micrometers and 300 micrometers, respectively. The beveling seems to smooth out the pressure gradients, with beneficial effects on the diamond. At megabar pressures, gradients over the active area dictate the use of a very small sample and this makes experimentation at these pressures a challenge. However, these challenges are being met by using ingenious methods.

Pressure Calibration. Pressure is determined in a remarkably simple way using ruby fluorescence. Indeed, without the ruby the small size of the high-pressure cell would make the pressure quite difficult to calibrate and the scientific value of the instrument would be far less than it is. When ruby is excited by light, it fluoresces strongly with a deep red color. The fluorescent emission can be resolved by a spectrograph into two peaks, called R_1 and R_2, whose wavelengths are accurately known at atmospheric pressure. When the pressure on the ruby is increased, the fluorescence peaks shift to a higher wavelength. This shift has been calibrated for pressures known on independent grounds, and hence, the measured shift of the peaks is an indirect measure of the pressure on the ruby. Usually the stronger of the two peaks, the R_1 peak, is used in pressure calibration. The spectral shift can be quickly and accurately measured with a simple grating spectrometer. The shift is almost exactly proportional to the pressure up to 300 thousand atmospheres (0.037 nanometer per atmosphere). For higher pressures the spectral shift is somewhat smaller for a given increment in pressure, but the shift has now been calibrated up to 2 megabars (nearly 2 million atmospheres) using gold as standard. The ruby seems to work quite satisfactorily to the highest pressures reached with the DAC, namely, 5 megabars, and an extrapolation of the above scale is used to measure these very high pressures.

Pressure Media

There are several materials currently employed as hydrostatic media in the cell. The most convenient material to load into the cell is a mixture of four parts methanol to one part ethanol, but at pressures of more than 105,000 atmospheres the mixture solidifies at room temperature and the pressure is no longer hydrostatic. For higher hydrostatic pressures, noble gases, viz. argon, xenon, or even hydrogen and helium are used. These gases can be trapped in the tiny hole in the gasket either by cooling the diamond cell to low temperatures and filling with the liquefied gas or by

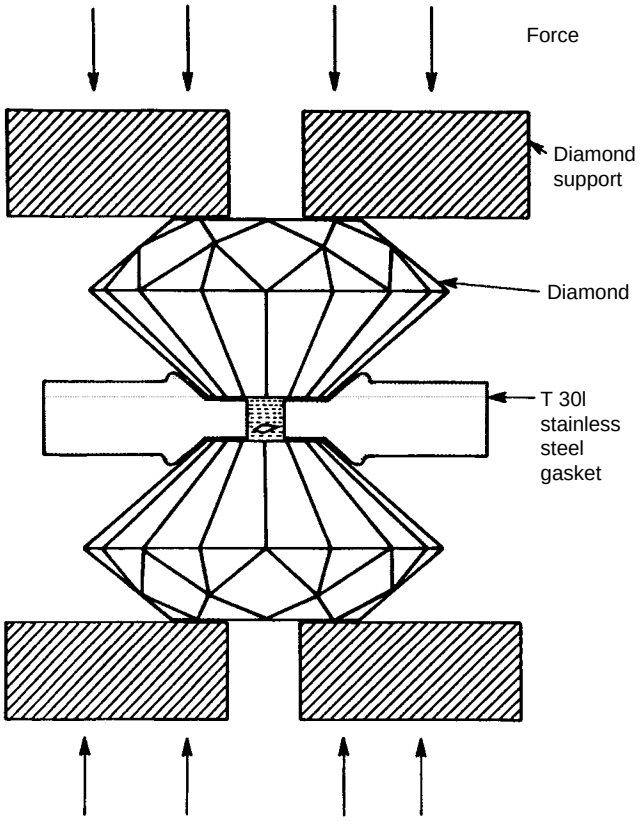

Fig. 2. Basic principle of the diamond cell. Pressure is generated in the gasket hole when the diamonds are pushed against one another. The sample and a small chip of ruby for pressure calibration are placed in the hole and the latter is filled with a pressure-transmitting medium. The purpose of the gasket is to provide containment for the pressure medium as well as support the diamond flats. Suitable apertures in the diamond support blocks provide access to optical, x-ray, and other radiation.

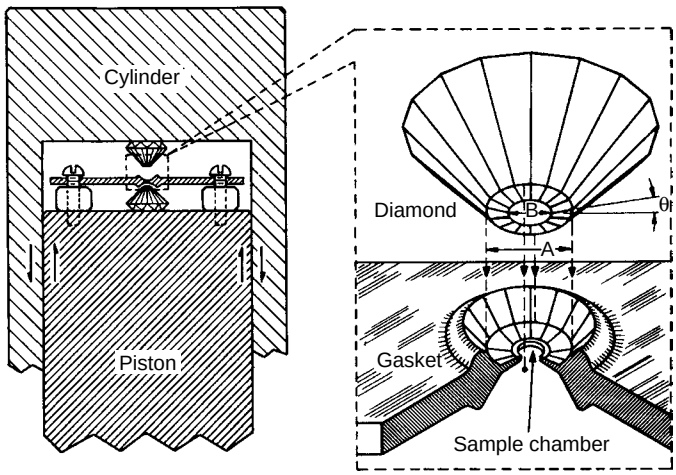

Fig. 3. For megabar pressures, the piston and cylinder assembly should be perfectly fitting, to maintain the alignment of the diamond anvils. The diamonds are beveled to smooth out the pressure gradients. The A dimension varies from 0.6 mm to 0.3 mm and the B dimension from 0.3 mm to 0.1 mm. The gasket hole varies from 0.1 mm to 0.025 mm. The bevel angle θ is usually around five degrees. After an experiment at megabar pressures, the diamonds develop ring cracks, but they can be reground and repolished for further use. (*After Mao and Bell*.)

the high pressure gas loading technique. In the latter method, the diamond cell is enclosed in a large pressure vessel and charged with the gas at about 2000 atmospheres. The high pressure gas, filling the gasket hole, is trapped by applying pressure to the gasket with the diamonds, from outside. After the release of pressure in the large pressure vessel, the diamond cell with the trapped high pressure gas is taken out and loaded into the lever-arm mechanism for further pressurization when running an experiment. The trapped gas can serve as a pressure medium, or it can be a sample for high pressure studies.

High Pressure-High Temperature. High pressure-high temperature conditions are particularly desirable for geophysical studies. In the diamond anvil cell such conditions can be produced by internal heating of the sample with a high power laser beam (such as a neodymium glass laser) or externally by surrounding the diamond anvil region with a heater element. In the first method, only the sample gets heated and not the diamond, because of its transparency to the laser radiation. Sample temperatures of 5000 °C have been attained at pressures of one megabar with laser heating. The temperature is measured either by optical pyrometry or by a radiometric technique. In the external heating method, the entire diamond anvil region is heated. The temperature attainable is limited to about 1000 °C because of the damage to the diamond and loss of mechanical support at high temperatures.

Low Temperature. It is also possible to operate the DAC at liquid helium temperatures (−270 °C) for high pressure-low temperature studies. For low temperature studies the diamond cell is placed inside a low temperature Cryostat provided with optical windows, and is pressurized by a suitably designed tightening mechanism.

Ultrahigh Pressure Research

The diamond anvil cell is a tool par excellence for optical, infrared and Raman spectroscopy and enables the researcher to study the changes in the electronic structure and chemical binding caused by the application of high pressure. Phase transitions, which involve changes in the atomic architecture can be determined with the diamond cell using the x-ray diffraction technique. The diamond cell has been successfully interfaced with synchrotron sources, which generate powerful x-ray beams, for x-ray diffraction studies. In geophysics, the high pressure-high temperature capabilities of the diamond cell is like a window to the interior of the earth. High pressure-high temperature studies give information on the state of silicate minerals and oxides in the mantle region right up to the core-mantle boundary and provide us with a view of the earth's interior, where high pressure and high temperature conditions exist. In solid state physics, one of the most fascinating problems is the possibility of making metallic hydrogen under ultrahigh pressure. This extraordinary change from a very good insulating to a metallic state in hydrogen is predicted to occur near 3 to 4 million atmospheres. High pressure scientists are trying hard to make metallic hydrogen with the DAC.

The limit of pressure attainable with the DAC could be much higher than 5 million atmospheres. Theoretical calculations reveal that diamond is stable up to 23 million atmospheres with respect to any phase transitions. Plastic deformation would limit its capability, but this limit could be much higher than the presently reported maximum pressure of 5 million atmospheres.

Since the introduction of the diamond anvil high pressure cell in the early 1980s, it has found wide usage in a variety of research fields. Possibly, the greatest pressure achieved to date was 4.16 megabars by researchers (Cornell Univ.) when "squeezing" a microscopic sample of molybdenum powder. By comparison, the pressure at the center of the Earth is estimated at about 3.6 megabars. Other extremely high pressures have been achieved at the Lawrence National Laboratory (Livermore, California).

In 1988, J.M. Brown and L.J. Slutsky (Univ. of Washington) and K.A. Nelson and L.T. Cheng (Massachusetts Institute of Technology) took advantage of the adaptability of laser-induced phonon spectroscopy and diamond anvil techniques to determine acoustic velocities and equations of state (methanol and ethanol). As pointed out by the researchers, "Acoustic velocities are directly related to interatomic force constants and these velocities of sound are a matter of considerable importance to the earth sciences." By knowing these properties, proceeding from a seismological image of the Earth's interior, a geophysical model in terms of density, temperature, and chemical composition can be created.

Godward (Univ. of California, Berkeley) and a team of researchers used a laser-heated diamond cell (modified Mao-Bel type) in their research on the ultrahigh-pressure melting of lead. This study is part of a project to *characterize* materials at ultrahigh pressures. Such data can be useful for a wide range of applications in the planetary sciences and the physics of condensed matter.

DIAPHRAGM. 1. The thin layers of muscle which suspend the insect heart within the body.

2. The muscular partition between the thoracic and abdominal cavities of mammals. The mammalian diaphragm is important in respiration. See also **Respiratory System**.

3. Metal, plastic, and rubber diaphragms find numerous industrial applications in various packings, in pressure gages, as seals, and in diaphragm actuators and diaphragm motor valves. See also **Valve (Control)**.

DIAPHRAGM CELL. A type of electrolytic cell for the production of sodium hydroxide and chlorine from sodium chloride brine. The cell contains anode and cathode compartments separated by a porous diaphragm or membrane to prevent mixing of the solutions. Asbestos fibers are usually used for this diaphragm, though a recent development is a plastic material made from perfluorosulfonic acid. The brine is fed continuously to the anode compartment, where chlorine is released at the graphite anode and flows through the diaphragm to the steel cathode, where hydrogen is liberated. Sodium hydroxide accumulates in the liquid and is continuously drained from the cathode compartment. The Hooker cell and the Vorce cell are two widely used types of diaphragm cell.

See also **Chlorine**.

DIAPHRAGM (Semipermeable). See **Semipermeable Membrane (or Semipermeable Diaphragm)**.

DIARRHEA. Increased frequency of bowel movements, accompanied by a loose consistency of the stools. The condition is particularly dangerous in infants and small children because of the rapidity with which serious dehydration may occur. Diarrhea occurs in connection with a number of human diseases and disorders and can be categorized in terms of principal causes and/or mechanisms: (1) osmotic diarrhea; (2) secretory diarrhea; (3) contact-deficiency diarrhea; and (4) exudative diarrhea. Quantitative data pertaining to the physiology of the normal adult small intestine and colon may be helpful to understanding diarrhea:

Source of Water	Rate (Liters/Day)
Dietary intake of water	2.0
+ saliva	1.0
+ gastric secretions in stomach	2.0
To duodenum	5.0
+ pancreatic secretions	2.0
+ biliary secretions	1.0
To jejunum	8.0
+ jejunum secretions	1.0
	9.0
− jejunum absorption	4.5
To ileum	4.5
− ileum absorption	3.5
To colon	1.0
− colon absorption	0.9
Excreted in stool	0.1

Osmotic Diarrhea. Certain ions, such as divalent magnesium (Mg^{2+}), divalent sulfate (SO_4^{2-}), and trivalent phosphate (PO_4^{3-}), are poorly absorbed by the small intestine. As a consequence, water is retained in the lumen by osmosis. This is exemplified by the effect of strong antacids, such as magnesium hydroxide, used in treating peptic ulcer disease, which can produce a water diarrhea. Saline laxatives also cause osmotic diarrhea. Another frequent cause of osmotic diarrhea is the ingestion of undigestible carbohydrates. If there is insufficient disaccharidase (enzymes) at the intestinal surface membrane, disaccharide (lactose or sucrose) will be retained within the intestinal lumen. The sugars must be converted to monosaccharide before they can be transported. This retention can account for 0.5–2 liters of diarrheal water per day. Also, action of certain bacteria in the small intestine may catabolize 12-carbon sugars to 3-carbon fragments, further enhancing the osmotic effect. See also **Carbohydrates**. With increasing age, commencing in the mid-teens, some individuals become lactase deficient and thus cannot handle the ingestion of milk and dairy products as well as they could when younger. This situation, of course, can be readily alleviated simply by reducing the intake of milk and related products. This cause of diarrhea can easily be confused with the so-called *irritable bowel syndrome*, which is described later. Other offenders in some individuals are legumes, which contain oligosaccharides (stachyose, raffinose, etc.) and nondigestible sugar alcohols (mannitol, sorbitol, etc.) which are now widely used as artificial sweeteners. These substances can cause osmotic diarrhea, particularly in children. The administration of lactulase as the therapy of hepatic encephalopathy can cause a watery diarrhea, but this usually is an acceptable side-effect.

Secretory Diarrhea. This condition results from the action of various substances that increase the secretion of water in the bowel system. The enterotoxins produced by certain bacteria (*Escherichia coli, Vibrio cholerae*, etc.), through a complex series of reactions involving intestinal receptors, increase the level of adenosine monophosphate (AMP) and consequently enhance the secretion of sodium, chloride, and water. See also **Cholera**. Other microorganisms (viruses and parasites) may cause secretory diarrhea. *Salmonella, Clostridium perfringens*, and staphylococci, among bacteria; viruses (see also **Coxsackie Virus**; and **Norwalk Virus**); fungi which causes candidiasis; and parasites which cause giardiasis and amebiasis, among others, also cause varying degrees of diarrhea–either as the principal or one of the major consequences of infection and invasion. See also **Amebiasis (Amebic Dysentery)**. It is estimated that about half the travelers who complain of diarrhea when in Mexico and a number of other developing countries are infested with *E. coli*. Symptoms are watery diarrhea and severe abdominal cramps. The disease runs a course of 4–5 days. Because of rapid dehydration, this disease in children should receive early attention. Most patients respond well to ampicillin therapy, although in infrequent cases antimicrobial therapy may be indicated. See also **Foodborne Diseases**.

The malabsorption of fats may cause a watery secretory diarrhea as the result of irritation of the distal small intestine by long-chain fatty acids. Stools are frequently voluminous and rise to the top of the water in the toilet bowl, causing difficulty in flushing the toilet. Another possible cause of secretory diarrhea stems from the use of certain irritating laxatives, such as cascara and castor oil. It has been reported that sometimes neomycin and para-aminosalicylic acid may antagonize the absorption of fats.

A condition known as *villous adenoma* (leading in about half the cases to carcinoma) is found in the rectum and/or colon and can cause severe secretory diarrhea. A congenital situation in which there is a malfunctioning bicarbonate-chloride mechanism in the ileum may result in excessive secretion of chloride ion and water. Known as *congenital chloridorrhea*, this is a rather uncommon disorder.

Contact-Deficiency Diarrhea. Insufficient contact and mixing action within the bowel system can cause diarrhea. This may result from certain operative procedures, such as resection of small intestine, surgical bypass, or by the presence of a "short circuit" (fistula, etc.) in the small intestine. In some individuals, rapid transit time in the bowel does not permit sufficient time for normal bowel action and results in diarrhea. Sometimes called *spastic colitis, mucus colitis*, or *irritable bowel syndrome*, symptoms include abdominal cramping, urgency to defecate, and loose, mucus covered stools (no blood). This rather poorly understood syndrome accounts for a high percentage of gastrointestinal complaints. Sometimes there is a cyclic nature to the condition, ranging from constipation to diarrhea. Some authorities suggest emotional stress in connection with the disorder, thus accounting for the transient nature of symptoms. Therapy varies considerably and is addressed to particular individual complaints.

Exudative Diarrhea. Principal causes of exudative diarrhea are ulcerative colitis and granulomatous colitis. See also **Colitis and Other Inflammatory Bowel Diseases**. The condition also arises in pseudomembranous colitis, and from invasive bacteria.

Pseudomembranous Enterocolitis. This complaint has several designations, including antibiotic, diphtheric, necrotizing, postoperative, and staphylococcal enterocolitis, depending upon particular circumstances. Because this is a multifaceted condition, sigmoidoscopy and other laboratory examinations are frequently required for diagnosis. Because the mortality rate of the disease can reach 50–75%, the condition, the symptoms of which are acute diarrhea (containing pus, mucus, and sometimes, fresh blood), high fever (up to 105 °F; 40 °C), and often dehydration and much less frequently, shock, requires immediate attention. Cardiac arrhythmias may also develop. In recent years, an association has been made between pseudomembranous enterocolitis and certain antibiotics, such as clindamycin and lincomycin; it is also believed that ampicillin, chloramphenicol, and tetracycline may also be implicated in some situations. It has been found that stool examinations of patients where the disorder is antibiotic-induced will show the presence of *Clostridium difficile*. It is considered that the latter may be a direct cause of the disease. The disease runs a course of 1 to 4 weeks. Therapy is usually administration of a broad-spectrum antibiotical.

Other drugs that can cause diarrhea include certain antimetabolites, colchicine, and ethanol, all of which can cause mucosal damage.

DIASPORE. The mineral diaspore is a hydrous oxide of aluminum corresponding to the formula AlO(OH) occurring in prismatic orthorhombic crystals, usually somewhat flattened, or massive. It displays good cleavage; conchoidal fracture; is brittle; hardness, 6.5–7; specific gravity, 3.3–3.5; luster, vitreous to pearly; color, white, grayish, greenish, yellowish, brownish or colorless; transparent to translucent. Diaspore is found associated with corundum, emery and bauxite, being probably an alteration product of the oxide. It has been made artificially. Diaspore has been found associated with emery in the Ural Mountains, in the Middle East, in the Island of Naxos, Greece, and in the United States at Chester, Massachusetts. Its name is derived from the Greek word meaning to scatter, because of its decrepitation upon heating.

DIASTEM. A term proposed for a slight hiatus, or loss of record, during the deposition of sediments. As diastems must be contemporaneous with sedimentation they are not to be confused with disconformities.

DIASTOLE. The stage of dilation of the heart or relaxation of the heart muscle. It is during this stage that the chambers of the heart fill with blood.

DIASTROPHISM. A general term for all types and modes of deformation of the earth's crust, including the formation of ocean basins, continents, plateaus, and mountain ranges. Use of the term preferably is limited to large-scale processes. *Tectonism* is a synonym.

DIATHERMAL WALL (also Adiathermal; Diathermaneous). A perfect heat conductor; assuring equality of temperature on both sides of it. Since in a rigorous development of the principles of thermodynamics it is necessary to introduce the concept of a diathermal wall before the concept of heat, it is necessary to adopt the following alternative definition. If two closed systems are placed in contact (i.e., interact) through a diathermal wall, their states cannot be varied independently of one another. If the state of one system is changed, then in general, the state of the other system will also change; the systems are coupled. If the state of one system is described by k properties x_i and the state of the other system is described by l properties yi, then coupling the two systems with the aid of a diathermal wall implies a functional relationship

$$f(x_1, x_2, \ldots, x_i, \ldots, x_k; y_1, y_2, \ldots, y_i, \ldots, y_l) = 0$$

The number of degrees of freedom (independent properties) of the combined system is now $k + l - 1$.

DIATHESIS. Congenital predisposition toward any disease.

DIATOM. Diatoms are algae that are very commonly found in both fresh and salt waters. Often they occur in immense numbers, especially in the ocean. The feature that distinguishes them from all other algae is the siliceous wall that encloses them. This is composed of two halves or valves, one of which fits over the other much as a cover fits onto a box. These siliceous walls are often beautifully marked with the finest and most regularly arranged patterns which makes these algae objects of great beauty when seen under a microscope. Because of the regularity of these marks, certain species are used for testing the resolving power of a microscope. Within the wall, the simple protoplast contains several chloroplasts, which may contain a brown pigment that masks the chlorophyll present.

Many diatoms are distinctly unicellular organisms; others stick together to form long chains or are included in a gelatinous sheath which forms extensive branching aggregations. There are two large orders of diatoms, separated according to the shape of the cell. One, the Centrales, comprises those diatoms which are radially symmetrical; the other, the Pennales, those which are not radially symmetrical. Many of the Pennales are bilaterally symmetrical, others irregular. Many members of the Pennales move about in a gliding manner.

Two methods of reproduction are found in diatoms. The more common method is asexual. In this process the protoplast of the cell enlarges, pushing the two valves apart. Then the protoplast divides into two parts, each of which occupies one of the two valves. A new valve is formed over the exposed surface of the protoplast but inside the original valve of the cell. As a consequence the new valve is smaller than the original. As repeated divisions occur the size of the valve gradually decreases. This does not continue indefinitely, however. To bring the cell back to its original size, auxospores are formed. When this happens, the protoplast enlarges tremendously and escapes from its walls. It then divides and secretes about itself new walls which have the size of the original cell. Auxospore formation is often a result of sexual fusions. Sexual reproduction is accomplished by the fusion of two diatoms. There are several variations in the method in which this process occurs. Sometimes it is a simple fusion of two protoplasts to form one; in other forms, two amoeboid gametes are formed by each protoplast. Gametes from different protoplasts fuse, forming zygospores. Several other variations are known. Some of the Centrales form small biciliate gametes, which fuse.

The diatoms are a very important group of algae. Occurring in immense numbers as they often do, they are the main food substance of many animals, which in turn become food for higher organisms, including man. When a diatom dies and its protoplast disintegrates, the siliceous shell sinks to the bottom of the water. Gradually immense accumulations of diatom valves are formed on the ocean bottom. These may eventually be buried beneath other deposits. They become diatomaceous earth, often forming beds hundreds of feet thick and covering large areas. Diatomaceous earth after removal of organic matter is used as an abrasive and scouring agent, as a filter, and in many other ways. See also **Diatomite**.

DIATOMITE. Diatomite is a naturally occurring, porous, high surface area form of hydrous silica that is used as a filter aid and as a mineral filler. diatomite products may be classified according to manufacturing method into three categories: natural diatomite [cas: 7631-86-9], calcined diatomite [CAS: 91053-39-3], and flux-calcined diatomite [CAS: 68855-54-9]. Products from all three categories find widespread use in industrial filtration applications as a filter aid for achieving higher clarity, longer filter cycles, and removing high solids concentrations. Products from all three categories are also used as functional fillers where diatomite properties add to the performance of paints, plastics, rubber, catalysts, agricultural chemicals, pharmaceuticals, toothpastes, polishes, and other chemicals. See also **Pharmaceuticals**.

Diatomite, also known as diatomaceous earth, or kieselguhr, consists mainly of accumulated shells or frustules of intricately structured amorphous hydrous silica secreted by diatoms, which are microscopic, one-celled golden brown algae of the class Bacillariophyceae. Diatoms exist in many different environments and are abundant in regions of oceanic upwelling: 12,000 to 16,000 species of diatoms live in fresh, brackish, or saline waters. Diatom species can live both solitarily and colonially; some are mobile, others stationary. All diatom species have an elaborately ornamented siliceous skeleton, which results in accumulations of uniquely porous particles.

In AD 532 the Roman emperor Justinian used diatomite bricks for lightweight construction of the dome when building the Church of St. Sophia in Constantinople (Istanbul). The names bergmehl, fossil flour, farine fossile, and mountain flour apparently originated when early poverty-driven peoples extended supplies of meal and flour by dilution with diatomaceous earth. Tripoli is a name given to diatomite formerly mined in Tripoli, North Africa. Kieselguhr, the name given to the diatomite first mined in Hanover, Germany, in 1836 or earlier, is still used as a general name for all diatomite products in Europe. An incorrect name that persisted for many years was infusorial earth; incorrect because Infusoria comprises a group of the animal kingdom (1). Nobel developed the first important industrial use of diatomite as an absorbent for liquid nitroglycerin in the making of dynamite late in the nineteenth century.

The first commercial shipment of diatomite in the United States was made in 1893 and consisted of material from a small quarry operation in the vast deposit near Lompoc, California. It went to San Francisco to be used for pipe insulation.

Most commercial marine diatomite deposits exploit accumulations resulting from large blooms of diatoms that occurred in the oceans during the Miocene geological epoch. Diatomite sediments older than the Jurassic period are rare in the fossil record. Commercial deposits of diatomite are accumulations of the fossil skeletons, which can occur in beds as thick as 900 m in some locations. Marine deposits must have been formed on the bottom of protected basins or other bodies of quiet water, undisturbed by strong currents, in an environment similar to the existing Santa Barbara Channel or Gulf of California.

The main deposits of freshwater diatomite were laid down in large lakes. Many of these deposits in the western United States formed during glacial times, when the local climate was wetter. Several tens of square kilometers in Nevada west of Tonopah are covered with diatomite as are other large areas in the Great Basin.

The principal marine deposits were formed during the Tertiary period and more particularly the upper Miocene epoch. Deposits of freshwater origin date from the Pliocene to Miocene epochs to more recent times, dating to as late as 100,000 years ago. U.S. commercial deposits are at or comparatively near the surface. Bog deposits are exploited and lake beds are dredged for use in other parts of the world.

Deposits of diatomite are known to exist on every continent and in nearly every country. Over half of the states in the United States reportedly contain diatomaceous earth deposits. In some cases, deposits of marine and freshwater origin occur almost side by side as do deposits of widely varying ages. Most of the deposits are not large enough or sufficiently pure to have commercial value. Production figures show the location of the deposits that meet commercial standards in both respects.

In the United States the most extensive commercial deposits are located in California, Nevada, Oregon, and Washington.

In Canada, large freshwater deposits are found in British Columbia, and small deposits are located in Nova Scotia, New Brunswick, Quebec, and Ontario. A small amount of diatomite production has been reported in Costa Rica, Chile, Brazil, and Argentina. Although deposits exist on other continents, the most important are in Europe, Africa, and Asia, primarily in Japan and Korea. Large deposits have been reported in the Caucasus Mountains of the former USSR. The leading producers in Europe operate in Romania, Germany, Italy, Iceland, and Denmark. Both Danish and Romanian diatomite production, although high in terms of tonnage, is of comparatively low value. Most Romanian diatomite is used as a binder in the construction industry and the Möler earth of Denmark is used as an absorbent, for bricks, and in agriculture. African deposits are located in Algeria and Kenya, and there are some small operations in the Republic of South Africa. Diatomite deposits also have been developed in Japan and China.

Chemically, diatomite consists primarily of silicon dioxide [CAS:7631-86-9], $SiO_2 \cdot nH_2O$, and is essentially inert. It is attacked by strong alkalies and by hydrofluoric acid but is virtually unaffected by other acids. The silicon dioxide has a unique structure, resulting from the intricate form of the diatom skeletons. The chemically combined water content varies from 2 to 10%. Impurities that are often found mixed with the diatomite are other aquatic fossils such as sponge residues, Radiolaria, silicoflagellata, sand, clay, volcanic ash, mineral aerosols, calcium carbonate, magnesium carbonate, soluble salts, and organic matter.

The color of pure diatomite is white, or near white, but impurities such as carbonaceous matter, clay, iron oxide, volcanic ash, etc may darken it. The refractive index ranges from 1.41 to 1.48, almost that of opaline silica. Diatomite is optically isotropic.

Individual diatom frustules are porous. The diatoms are highly variable in shape and size, having particles that range in effective diameter from 0.75 to 1000 μm, but most are 50 to 100 μm in diameter. Diatom shapes can range from simple cylinders and disks to complex, highly variable, but always punctate, forms. The highly variable array of shapes gives marine diatomite an advantage in certain filtration applications over freshwater diatomite. The latter usually contains fewer genera and less variation in size and shape.

The bulk density of powdered diatomite varies from 112 to 320 kg/m^3. The true specific gravity of diatomite is 2.1 to 2.2, the same as for opaline silica, or opal. The thermal conductivity of bulk quantities of diatomite is low but increases with higher percentages of impurities and a higher density. The fusion point depends on the purity but averages about 1430 °C for pure material, which is slightly less than for pure silica. The addition of chemical agents, such as soda ash, reduces the fusion point.

Diatomite has only weak adsorption powers but shows excellent absorption because of its structure and high surface area. Acids, liquid fertilizers, alcohol, water, oils, and other fluids are absorbed by diatomite. See also **Absorption;** and **Adsorption**.

Diatomite deposits are usually discovered by observation of outcrop, and the value of the deposits is determined by geological prospecting and exploration.

Most diatomite is mined by open-pit methods.

Three general types of diatomite are produced, and a range of grades exists in each. Grade, as used herein, refers not to the quality of the product but designates one of the series of products made for specific uses. Producers often supply custom-made materials for specialized applications.

The crude diatomite, which may contain up to 60% moisture, is first milled in a method that preserves the intricate structure of the diatomite. This material is fed to dryers operating at relatively low temperatures, where virtually all of the moisture is removed. Coarse and gritty nondiatomaceous earth material is removed in separators and preliminary particle size separation is made in cyclones. For many producers, all of the manufacturing processes, with the exception of the calcination step, take place while the material is being pneumatically conveyed. The resultant material is termed natural product. This is the only type of diatomite made by some producers.

Calcined diatomite is produced from natural diatomite, which is then subjected to high temperature calcination in a rotary kiln at about 980 °C. The calcined material is then again milled and classified to remove coarse agglomerates as well as extreme fines.

The third type of product, flux-calcined diatomite, is obtained by calcination of the natural product in the presence of a fluxing agent, generally soda ash, although sodium chloride can also be employed. Such processing has the effect of reducing the surface area of the particles, changing the color from the natural tan color to a true white, and rendering various impurities insoluble. Some of the diatomite is converted on calcination to cristobalite [CAS: 14464-46-1]. Most diatomite contains a small percentage of quartz (less than 5%), calcined diatomite can contain up to 25% cristobalite, and flux-calcined diatomite can contain up to 65% cristobalite.

Diatomite products have unique characteristics of high surface area, low bulk density, high water and oil absorption, and high permeability. Each fossil particle, because of its silica composition, is a rigid but porous and irregular shape. In general, diatomite products can be grouped according to use as filter aids, fillers or extenders, adsorbents, catalyst carriers, insecticide carriers or dilutents, fertilizer conditioners, thermal insulation, and miscellaneous. In physical form, powders make up by far the greatest proportion of diatomite products.

There are two principal ways in which finished diatomite products are used in manufacturing plants: either as a filter aid, where the diatomite is

expendable, or as a filler, where the diatomite becomes a component and remains as part of the manufactured product.

The paint and plastics industries are typical of those employing diatomite extensively as fillers and pigment extenders. Diatomite is useful as a filler in paint where it forms a rougher surface, provides a flatting effect, and because of its porous intricate structure, allows faster drying and may improve intercoat adhesion. Also diatomite is extensively used as a polyethylene antiblocking agent where the irregular shapes of the diatom act as a mechanical barrier that prevents sticking of hot polyethylene films during production.

Diatomaceous earth has been used as a chromatographic support since the inception of gas chromatography. A diverse line of products are available. The high surface area and structure of diatomite enables it to carry the liquid phase while an inert surface prevents interference with partitioning. Properly treated diatomite chromatographic supports make use of all its unique properties. See also **Diatom**.

DIATREME. A general term for volcanic pipes and circular vents, the result of the explosive action of magmatic gases.

DICHOTOMY. 1. In astronomy, a configuration of three bodies so that they form a right triangle; specifically, such a configuration in the solar system with the sun at the apex of the 90° angle.

2. A system or method of branching in which the main axis divides into two branches, which may in turn branch in the same manner, as for example the thallus of an alga or an hepatic, or the root or stem of a club moss.

DICHROISM. The property of exhibiting two colors, especially of exhibiting one color when viewed in reflected light and another when viewed in transmitted light, as in the case of solutions of chlorophyll. Substances which have this property are termed dichroic. They may also be said to exhibit dichromatism. See also **Cordierite**.

DICHROMATISM. This term has two uses in optics, as follows: 1. A type of color blindness in which the eye can distinguish two and only two colors. 2. A substance with two broad, but not equally deep, absorption bands in the visible may appear to have a different color as observed by transmitted light depending on the thickness of the plate of material. Such a material is called dichromatic or dichroic.

DICOTYLEDONS. The larger of the two subclasses of angiosperms is the dicotyledons, containing over 150,000 species. The plants of this subclass have leaves, flowers and seeds distinctly different from those of monocotyledons. The leaves are generally broad and have netted veins; the parts of the flowers occur most frequently in fours or fives or multiples of these numbers. That is, there are 4 or 5 sepals, 4 or 5 petals, 4 or 5 (8 or 10, or more) stamens, and one to many pistils. The embryo of the seed has two cotyledons or seed leaves.

Many important food plants are members of this group; for example, potato, cabbage, carrot, apples, oranges, and peanuts. Other dicotyledons yielding economic products of great value are the various rubber plants, cotton, flax, sugar beets, and soy beans. The number cultivated as ornamental plants is too great to enumerate here.

Dicotyledons vary in size from tiny annuals an inch or less in height to giant trees 350 feet (105 meters) tall. They include herbaceous and woody members, annuals, biennials, and perennials. They are found all over the world, wherever plants can grow. See also **Angiosperms**.

DICROSCOPIC EYEPIECE. An eyepiece for a polariscope or polarizing microscope which gives a comparison view of the same object or field under illumination by the two complementary rays of polarized light.

DIDYMIUM. See **Neodymium**.

DIDYMIUM GLASS. Didymium glass is a special optical glass that is tinted with mixed oxides of neodymium and praseodymium to give very narrow and sharp absorption bands. One in particular falls at the wavelength of yellow sodium light, so that the glass, which is only faintly tinted to white light, is almost opaque to the yellow sodium light.

DIE. There are several commonly accepted usages of this term. In thread cutting, a die is a tool resembling a slotted nut, and is used for cutting external threads on screws, bolts, and pipe. In wire drawing, a die is a device used to procure plastic flow of metal; the die is usually, although not necessarily, made with a bell-mouth circular hole, into which the end of the wire is introduced. In the past, hardened steel dies for wire drawing were extensively used; at the present time, either tungsten-carbide or diamond dies are used, since the wear and abrasion on the die are considerably reduced.

DIE CASTING. Die castings are produced by forcing molten metal under pressure into a steel die. The pressure is maintained until solidification is complete. The process is essentially a further development of gravity-feed casting, but the pressure function entails finer detail and better finish. While gravity-feed casting tonnage is greater than that of pressure casting, the latter has a wider field of application and is more important in the quantity production of precision parts. Zinc alloys are generally used for die castings, although aluminum alloys, brass alloys and other non-ferrous metals are used to a considerable extent.

The process of die casting is entirely automatic and requires the following elements: a die-casting machine to hold the molten metal under pressure; a metallic mold or die capable of receiving the molten metal, and designed to permit easy and economical ejection of the solidified product; and a casting alloy that will produce a satisfactory product with suitable physical characteristics.

There are two types of die-casting machines. The first, or air-operated machine, forces the material into the die by high pressure on the surface of the molten metal in a special ladle or goose; the second, or plunger type machine, forces the material into the die by means of a cylinder and piston which are submerged in the molten metal.

Die-casting dies are constructed in different styles for various production requirements. A single die contains an impression of only one part; a multiple die contains two or more impressions of any one part; a combination die contains one impression only of two or more parts; and a combination-multiple die contains a number of impressions of each of two or more parts. Single dies are comparatively cheap and are used for small-lot production, since they reduce the tool investment to a minimum for any one part. Combination dies, when properly planned, will reduce the total die cost for a given set of castings to a minimum. They are applicable to parts that will always be used in the same quantities and of the same alloy. These parts should be of the same general character and weight. Multiple dies are usually slower to operate than single dies but will give higher production rates for the same labor costs.

Die-casting dies are often vented by permitting air to escape through the clearance in the ejector and core pin bearings. The problem of venting is considerably more important than in sand casting because the mold has no porosity. Sometimes dies are vented by grinding shallow grooves on the parting surfaces of the dies; in other instances plugs with suitable vent grooves are added to the die.

In 1986, direct injection zinc die casting reached commercial status with the production of gear casings for fractional horsepower electric motors. The process features use of a heated manifold and mini-nozzles to feed molten zinc directly into the die. The Zinc Institute (New York) reports that direct injection eliminates traditional runner and gating pathways and the scrap associated with them. The process is netting a 10% saving in scrap, remelt, and processing costs. Since the

molten zinc is injected directly into the die, it can fill the cavity without any chilling before contacting cavity walls. The result is a more uniform structure in the cast part and fewer rejects. Also, cast surface finish is smooth so that preplate finishing operations can often be eliminated.

DIELECTRIC FILMS. See **Thin Films**.

DIELECTRIC HEATING. The heating of a dielectric material by molecular friction in it as a result of the application of a high-frequency, alternating electric field. Dielectric heating is applicable to nearly all nonconducting materials, such as plastics, wood, and certain liquids. The method is extensively used for the preheating of plastic materials because the materials must be heated uniformly. Prior conventional methods required hours instead of a few minutes with dielectric heating. The method also is used in the printing and dyeing industry, and in the lumber and associated industries for speeding and perfecting the drying of glued joints.

Normally the power required for dielectric heating is provided by some form of oscillator, although the power can be obtained from an amplifier driven by an oscillator. The principal engineering is involved in the design of an oscillator circuit that will provide the proper energy level and in the design of the configuration whereby the energy can be most efficiently imparted to the workpiece.

See also **Microwave Radiation**.

DIELECTRIC THEORY. A dielectric is a material having electrical conductivity low in comparison to that of a metal. It is characterized by its dielectric constant and dielectric loss, both of which are functions of frequency and temperature. The dielectric constant is the ratio of the strength of an electric field in a vacuum to that in the dielectric for the same distribution of charge. It may also be defined and measured as the ratio of the capacitance C of an electrical condenser filled with the dielectric to the capacitance C_0 of the evacuated condenser:

$$\varepsilon = C/C_0$$

The increase in the capacitance of the condenser is due to the polarization of the dielectric material by the applied electric field. The terms "specific inductive capacity" and "permittivity" are occasionally used instead of *dielectric constant*. The constant ε appearing in the Coulomb law of force is called the permittivity, but it is also commonly called the dielectric constant. The relative permittivity or dielectric constant is the ratio $\varepsilon/\varepsilon_0$, where ε_0 is the permittivity or dielectric constant of free space. In the mks system of units, the dielectric constant of free space is 8.854×10^{-12} farad/m, while in the esu system the relative and the absolute dielectric constants are the same. The relative dielectric constant, which is dimensionless, is the one commonly used. When variation of the dielectric constant with frequency may occur, the symbol is commonly primed. When a condenser is charged with an alternating current, loss may occur because of dissipation of part of the energy as heat. In vector notation, the angle d between the vector for the amplitude of the charging current and that for the amplitude of the total current is the loss angle, and the loss tangent, or dissipation factor, is

$$\tan\delta = \frac{\text{Loss current}}{\text{Charging current}} = \frac{\varepsilon''}{\varepsilon'}$$

where ε'' is the loss factor, or dielectric loss, of the dielectric in the condenser and ε' is the measured dielectric constant of the material.

At low frequencies of the alternating field, the dielectric loss is normally zero and ε' is indistinguishable from the dielectric constant edc measured with a static field. Debye has shown that

$$\frac{\varepsilon_{dc}-1}{\varepsilon_{dc}+2} = \frac{4\pi N_1}{3}\left(\alpha_0 + \frac{\mu^2}{3kT}\right) \tag{1}$$

where N_1 is the number of molecules or ions per cubic centimeter; α_0 is the molecular or ionic polarizability, i.e., the dipole moment induced per molecule or ion by unit electric field (1 esu = 300 volts/cm); μ is the permanent dipole moment possessed by molecule; k is the molecular gas constant, 1.38×10^{-16}, and T is the absolute temperature. An electric dipole is a pair of electric charges, equal in size, opposite in sign, and very close together. The dipole moment is the product of one of the two charges by the distance between them.

In Equation (1), $\mu^2/3kT$ is the average component in the direction of the field of the permanent dipole moment of the molecule. In order that this average contribution should exist, the molecules must be able to rotate into equilibrium with the field. When the frequency of the alternating electric field used in the measurement is so high that dipolar molecules cannot respond to it, the second term on the right of the above equation decreases to zero, and we have what may be termed the optical dielectric constant ε_∞ defined by the expression

$$\frac{\varepsilon_\infty - 1}{\epsilon_\infty + 2} = \frac{4\pi N_1}{3}\alpha_0 \tag{2}$$

ε_∞ differs from n^2, the square of the optical refractive index for visible light, only by the small amount due to infrared absorption and to the small dependence of n on frequency, as given by dispersion formulas. It is usually not a bad approximation to use $\varepsilon_\infty = n^2$. The general Maxwell relation $\varepsilon' = n^2$ holds when ε' and n are measured at the same frequency. The Debye equation may be written in the form

$$\frac{\varepsilon_{dc}-1}{\epsilon_{dc}+2} - \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2} = \frac{4\pi N_1}{9kT}\mu^2 \tag{3}$$

A much better representation of the dielectric behavior of polar liquids is given by the Onsager equation

$$\frac{\varepsilon_{dc}-1}{\varepsilon_{dc}+2} - \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2} = \frac{3\varepsilon_{dc}(\varepsilon_\infty + 2)}{(2\varepsilon_{dc} + \varepsilon_\infty)(\varepsilon_{dc}+2)}\frac{4\pi N_1\mu^2}{9kT} \tag{4}$$

Anomalous dielectric dispersion occurs when the frequency of the field is so high that the molecules do not have time to attain equilibrium with it. One may then use a complex dielectric constant

$$\varepsilon^* = \varepsilon' - j\varepsilon'' \tag{5}$$

where $j = \sqrt{-1}$. Debye's theory of dielectric behavior gives

$$\varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_{dc} - \varepsilon_\infty}{1 + j\omega\tau} \tag{6}$$

where ω is the angular frequency (2π times the number of cycles per second) and τ is the dielectric relaxation time. Dielectric relaxation is the decay with time of the polarization when the applied field is removed. The relaxation time is the time in which the polarization is reduced to $1/e$ times its value at the instant the field is removed, e being the natural logarithmic base.

Combination of the two equations for the complex dielectric constant and separation of real and imaginary parts gives

$$\varepsilon' = \varepsilon_\infty + \frac{\varepsilon_{dc} - \varepsilon_\infty}{1 + \omega^2\tau^2} \tag{7}$$

$$\varepsilon = \frac{(\varepsilon_{dc} - \varepsilon_\infty)\omega\tau}{1 + \omega^2\tau^2} \tag{8}$$

These equations require that the dielectric constant decrease from the static to the optical dielectric constant with increasing frequency, while the dielectric loss changes from zero to a maximum value ε''_m and back to zero. These changes are the phenomenon of anomalous dielectric dispersion. From the above equations, it follows that

$$\varepsilon''_m = (\varepsilon_{dc} - \varepsilon_\infty)/2 \tag{9}$$

and that the corresponding values of ω and ε' are

$$\omega_m = 1/\tau \tag{10}$$

and

$$\varepsilon''_m = (\varepsilon_{dc} + \varepsilon_\infty)/2 \tag{11}$$

The symmetrical loss-frequency curve predicted by this simple theory is commonly observed for simple substances, but its maximum is usually lower and broader because of the existence of more than one relaxation time. Various functions have been proposed to represent the distribution of relaxation times. A convenient representation of dielectric behavior is obtained, according to the method of Cole and Cole, by writing the complex dielectric constant as

$$\varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_{dc} - \varepsilon_\infty}{1 + (j\omega\tau_0)^{1-\alpha}} \tag{12}$$

where τ_0 is the most probable relaxation time and α is an empirical constant with a value between 0 and 1, usually less than 0.2. When the values of ε'' are plotted as ordinates against those of ε' as abscissas, a semicircular arc is obtained intersecting the abscissa axis at $\varepsilon' = \varepsilon_\infty$ and $\varepsilon' = \varepsilon_{dc}$. The center of the circle of which this arc is a part lies below the abscissa axis, and the diameter of the circle drawn through the center from the intersection at ε_∞ makes an angle $\alpha\pi/2$ with the abscissa axis. When a is zero, the diameter lies in the abscissa axis, there is but one relaxation time, and the behavior of the material conforms to the simple Debye theory. When, as may arise from intramolecular rotation, a substance has more than one relaxation mechanism, or, when the material is a mixture, the observed loss-frequency curve is the resultant of two or more different curves and, therefore, departs from the simple Debye or Cole-Cole curve.

If the dielectric material is not a perfect dielectric, and has a specific dc conductance $k'(\text{ohms}^{-1}\text{cm}^{-1})$, there is an additional dielectric loss

$$\varepsilon''_{dc} = \frac{3.6 \times 10^{12}\pi k'}{\omega} \tag{13}$$

The effective specific conductance is given by

$$k' = \frac{1}{4\pi}\frac{(\varepsilon_{dc} - \varepsilon_\infty)\omega^2\tau}{1 + \omega^2\tau^2} \tag{14}$$

It is evident from this equation that k' increases with ω, approaching a limiting value, k_∞, the infinite-frequency conductivity, which is attained when 1 can be neglected in comparison with $\omega^2\tau^2$, so that

$$k_\infty = \frac{\varepsilon_{dc} - \varepsilon_\infty}{4\pi\tau} \tag{15}$$

In a heterogeneous material, interfacial polarization may arise from the accumulation of charge at the interfaces between phases. This occurs only when two phases differ considerably from each other in dielectric constant and conductivity. It is usually observed only at very low frequencies, but, if one phase has a much higher conductivity than the other, the effect may increase the measured dielectric constant and loss at frequencies as high as those of the radio region. This so-called Maxwell-Wagner effect depends on the form and distribution of the phases as well as upon their real dielectric constants and conductances. Each type of form and distribution requires special treatment. For a commercial rubber, for example, the observed loss may be

$$\varepsilon''\ (\text{observed}) = \varepsilon''_{dc} + \varepsilon''(\text{Maxwell} - \text{Wagner}) + \varepsilon''\ (\text{Debye}) \tag{16}$$

DIELS-ALDER REACTION. An important organic reaction for the synthesis of six-membered rings, discovered in 1928. It involves the addition of an ethylenic double bond to a conjugated diene, i.e., a compound containing two double bonds separated by one single bond, as in 1,3-butadiene (CH_2 =CH−CH=CH_2) or cyclopentadiene. The ease of addition of the ethylenic compound is greatly enhanced by adjacent carbonyl groups; hence maleic anhydride reacts quantitatively with hexachlorocyclopentadiene to form chlorendic anhydride.

DIELS, OTTO PAUL HERMANN (1876–1954). Otto Diels was a German organic chemist and Nobel Prize winner who discovered the Diels–Alder reaction used in diene synthesis. Diels, the son of the great classics scholar Hermann Diels (1848–1922), was born in Hamburg on 23 January 1876. He studied chemistry with Emil Fischer at the University of Berlin, gaining his doctorate in 1899. In 1904, following research with Fischer, he began teaching at the University of Berlin, where he became Professor of Organic Chemistry in 1906. In 1916 he became Director of the Chemical Institute of the University of Kiel. Although he formally retired in 1944, he contributed greatly to the postwar recuperation of the Institute. He was married with five children and liked to paint at weekends. He died at Kiel on 7 March 1954. See also **Fischer, Emil Hermann (1852–1919)**.

Diels wrote a popular textbook of organic chemistry in 1907 shortly after discovering carbon suboxide, C_3O_2, as a product of dehydrating malonic acid. The textbook remained in print until the 1960s. In the 1920s he used selenium to dehydrate cholesterol into 'Diel's hydrocarbon', $C_{18}H_{16}$, which he later showed to be a derivative of phenanthrene. This helped others to establish the structure of cholesterol as well as many other significant natural products. In 1928, while working with his Kiel assistant Kurt Alder, Diels developed a general synthetic reaction that was especially useful in producing stable six-membered hydroaromatic rings that abound in biochemically active compounds. In this addition reaction a double-bonded compound (dienophile) combined across the 1,4-positions of the conjugated diene to form a cyclohexane product. In Diels and Alder's first example, butadiene combined with maleic anhydride to form cis-1,2,3,6-tetrahydrophthalic anhydride. He and Alder shared the Nobel Prize for Chemistry in 1950 for their development of this synthetic pathway. See also **Alder, Kurt (1902–1958)**; and **Organic Chemistry**.

DIENCEPHALON. A portion of the forebrain of vertebrate animals. The diencephalon is of great importance in the sensory and automatic adjustments of the body. One part, the thalamus, is a major relay station for sensory impulses going to the cerebrum, and it is also concerned with motor coordination. The hypothalamus integrates the various automatic body reactions. For instance, when a dog becomes overheated he begins to pant and his tongue hangs from his mouth. There is also an increased saliva flow which helps to cool the blood flowing through the tongue. If the hypothalamus is injured, however, such reactions do not occur. The dog may become so overheated that he suffers heat prostration, yet his body never undergoes any of these cooling reactions.

DIESEL ENGINE. In a patent dated 1892, Dr. Rudolf Diesel, a German engineer, described an engine to operate on the Carnot cycle. Coal dust was the fuel, and it was to be fed rapidly enough so that isothermal expansion would result. After fuel cut-off, an adiabatic expansion would continue, followed by a compression made isothermal by the injection of water into the cylinder. An adiabatic compression then brought the cycle back to its beginning. A further claim of the patent covered the use of liquid fuels and the spray valve. Early attempts to build this engine resulted in the adoption of a modified cycle which, after much experimentation, was built into a successful working engine.

Although modified from the inventor's original conception, the modern diesel cycle retains the most important feature, namely that of compression of air to the ignition temperature, followed by timed introduction of fuel. This cycle is shown in Fig. 1. The solid line indicates a theoretical cycle, the dotted line shows how a slow-speed actual cycle may depart from the theoretical. Typical temperatures are also indicated. Beginning with point *D* on the cycle, imagine that a cylinder filled with air is closed at the end by a tightly fitting piston. The piston is moved to compress the air without addition or loss of heat through the cylinder walls. As the air is decreased in volume, the pressure rises adiabatically, and it arrives at the condition

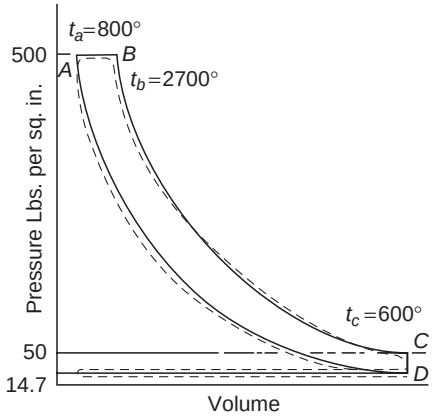

Fig. 1. Departure of actual diesel cycle from theoretical on-air standard cycle.

corresponding to point *A*. The piston is then reversed in direction, and starts to move so as to increase the volume of the air. The air is very hot due to its adiabatic compression. In fact, it is well above ordinary ignition temperatures of petroleum products. As the piston starts to move, carrying the cycle from point *A*, fuel is injected or sprayed into the cylinder just rapidly enough so that its combustion will keep the pressure up while the volume is being increased, at least up to point *B*. At *B* when the outward stroke is partially completed, the fuel is cut off, and the products of combustion expand adiabatically from *B* to *C*, giving work to the piston as they do. At *C* the exhaust valve opens, and the pressure drops to *D*. The line extending horizontally from *D* represents the theoretical exhaust and suction stroke. Adiabatic expansion and compression are not possible in a cylinder that must be well cooled in order to maintain a lubricating oil film. Therefore an actual cycle will not be expected to follow the adiabatic. Another difference between actual and theoretical cases is the composition of the gas within the cylinder. Theoretical studies are made assuming pure air in the cylinder. Actually there is a little burned gas present during the compression, and a great deal of it during the expansion strokes. However, by assuming no friction loss, adiabatic compression and expansion, and air, only, in the cylinder, an expression may be derived for the efficiency of the cycle *ABCD*. Note that the temperatures in the diagram are in degrees F.

The stationary diesel engine is usually a heavily built engine having a piston which reciprocates in a cylinder. A connecting rod is either pinned directly into a trunk type piston, or to a crosshead to which the piston is connected by a piston rod. The connecting rod bears on a crank, which has bearings in the main frame. Added to these parts are the auxiliaries such as valves and valve gear, fuel injection systems, water circulation systems, starting systems, etc. The diesel is more heavily built than the gasoline engine, and is a relatively slow-moving machine. Rotative speeds are commonly 100 to 750 rpm, except that automotive diesels are designed for 2000 rpm and over. The fuel ordinarily employed is a product from crude petroleum.

Fuel is pumped into the cylinder during the first part of the power stroke, correctly metered so that its combustion tends exactly to offset the drop of pressure which would otherwise be experienced. During combustion of the fuel in the diesel engine the pressure remains approximately constant. After a small portion of the power stroke is completed, the fuel is cut off, and the products of combustion do work on the piston expansively.

The principal and important difference between the oil and the gasoline engine resides in the method of ignition. Compression of the air trapped in the cylinder of a diesel engine is employed as its means of ignition. The compression is carried to much higher pressures in the diesel than in the Otto cycle; consequently, the temperature at the end of compression is higher in the diesel cycle. In fact, compression is carried high enough so that the temperature of the compressed gas exceeds the ignition temperature of the fuel. This is compression ignition. It may require the volume after compression to be only one-fourteenth of that before compression, whereas it is only a fifth or a sixth in the gasoline engine. It is not possible to use compression ignition in the ordinary Otto cycle engine, because an inflammable charge is compressed, and the compression to the ignition temperature would cause spontaneous, uncontrolled, unregulated ignition. However, the charge compressed in the diesel is fresh air — incombustible. This air is compressed until its pressure is over 500 psi (34 atmospheres), and its temperature around 800 °F (427 °C). Then the oil is injected into the hot compressed air whose temperature is sufficiently high to cause immediate ignition of the spray.

The heart of a diesel engine is the combustion chamber end of its cylinder. The shape of the cylinder head and face of the piston and the design of the nozzle and the injection system must be carefully considered. To obtain the complete combustion necessary to good efficiency, a fuel must be thoroughly mixed with the air charge, so that all particles of it will be burned. There must be good penetration of the oil spray into the highly compressed dense air, and there must be turbulence to insure mixing of the oil spray with the air. These two important characteristics are secured by special design, both of the cylinder head and the spray valve.

In the two-cycle engine there is no valve gear. The absence of this feature is, indeed, the virtue of the two-cycle principle. In the four-cycle engine the exhaust and inlet valves are mechanically operated from a camshaft. Since the diesel engine is commonly rather large, the valves are correspondingly large in girth, and are operated from a massive camshaft. Although the diesel engine is basically a slow-speed type, refinements of design, especially in the combustion chamber, have enabled builders to produce medium- and high-speed compression ignition engines.

Diesel engine design engineers are confronted daily with decisions that do not lend themselves well to the conventional approaches to design. These needs have caused the component/system analysis process to become an important ingredient in engine design. One of the most valuable tools today to analyze complex engine components is the finite element method. This method allows an analyst to study the behavior of engine components in their operating environmental and helps optimize the design prior to actual component procurement.

Ceramics have become a very attractive material in the diesel engine industry because of their ability to withstand elevated temperatures, low thermal conductivity, excellent corrosion and wear resistance, abundant availability, and potential for lower costs. However, progress in this area has been slow because ceramics possess very low fracture toughness along with a lack of ductility. Nevertheless, ceramic and composite materials are improving constantly and it is predicted that within the relatively near future many of these materials will be found in diesel engines.

Direct-Injection Diesel Engine

Unlike the traditional passenger car diesel engine which employs a precombustion chamber (creates turbulence in air charge and thus assures rapid mixing with the fuel jet in the interest of achieving complete combustion and reduction of smoke emissions), there is no prechamber in the direct-injection system. This system injects fuel into the clearance volume as the piston nears its top position. Used for several years in intermediate-size and heavy-duty diesel engines, direct injection is now under serious consideration for lighter vehicles. Because of higher operating temperature, there is an increase in nitrogen oxide (NO_2) emissions.

Considerable opportunity remains for improvement of the standard prechamber diesel engine, including improved combustion chamber design to reduce losses; optimizing the timing and duration of fuel injection; and improved torque characteristics through turbocharging, already incorporated in some designs. Recently available ceramic components may help designers to improve the engine's thermal efficiency.

Advancements in Turbocharging[1]

Since turbocharging was first used on truck diesel engines, their specific rating, brake mean effective pressure (bmep), has increased markedly. Interest in higher ratings will remain unchanged so long as higher power concentrations, lower fuel consumption, and lower production costs are needed. Conventional turbocharging methods have a number of well recognized problems, including relatively weak starting torque, slow response, and low exhaust braking power, factors that are essentially related to engine size. To these can be added peak torque, smoke, exhaust gas temperature, fuel consumption, and emission problems. Within the automotive community, there is a widely shared opinion that further significant increases in engine ratings will be closely related to future advances in turbocharging technology.

Several advanced turbocharging methods, such as resonant intake manifold, variable geometry turbine, two-stage, and wastegate have been developed. Sequential turbocharging is looked upon with promise.

A sequential turbocharging system comprises at least two turbocharging units, in a parallel arrangement, all operating at rated power. See Fig. 2. A gas flow control system makes it possible to cut off, sequentially, one or several of them as engine speed decreases. Thus, a sequential reduction (in discrete steps) of total turbine area is achieved with a corresponding rise of the turbine pressure ratio and, consequently, of the compressor pressure ratio, desired for significant improvement of engine low-speed performance and response. The method also allows for good matching of the turbochargers at rated power, offering a potential for lower fuel consumption and a lower thermal load at this operational point. Such a system is quite attractive for highly rated engines.

Well known in marine applications, the method has traditionally been considered unsuitable for land vehicles. Principal reservations have been higher costs, system bulkiness, and loss of pulse effect. Additional concerns relate to transient operation and the shape of the full-load curve, which pose special problems in selecting the right engine speed to define the turbocharging sequences and matching of the turbochargers (TCs).

[1] Source of information: Volvo Truck Corp. single-entry turbine TCs in combination with a pulse converter as shown in the diagram.

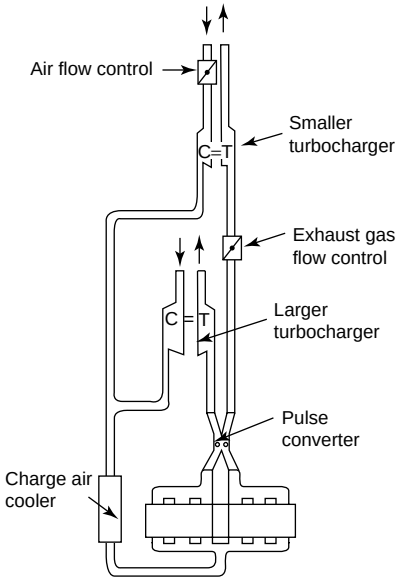

Fig. 2. Sequential turbocharging system for diesel engines has unequally sized turbochargers and a pulse converter.

In vehicular applications, optimization of the conventional turbocharging method sometimes leads to a system with two smaller, identical TCs in parallel. With such a system, the concept of switching off one of them to improve engine low-speed performance and response comes almost naturally. However, controlling gas flow at both turbines makes the control system rather complex.

In tests of various concepts, Volvo engineers concluded that it is essential that pulse operation, unequal turbocharger sizes, and low complexity be primary factors in developing an improved TC system. Two solutions were considered within this framework for use on truck diesel engines of no more than 8 cylinders: (1) a sequential system with twin-entry turbine TCs and direct connection of each exhaust manifold branch to one entry of each turbine. Each turbine is connected to the engine exhaust as in conventional turbocharging. (2) A sequential system with single-entry turbine TCs in combination with a pulse converter as shown in the diagram.

A pulse converter is a junction of at least two pipes (each from 1–3 exhaust ports) of a normal pulse turbocharging system, that normally would be connected to separate turbine inlets. The junction incorporates a suitable reduction inflow area in the downstream direction, converting some of the pressure of the exhaust pulses into kinetic energy. By taking advantage of the high momentum of gas flow through the nozzle, the effect of a pressure pulse entering the junction on the other manifold pipes is reduced. A pulse converter makes it possible to maintain pulse operation of a turbocharging system, yet allows for use of single-entry turbines. Pressure pulse variation at turbine inlet is reduced due to flow restriction imposed by a pulse converter which, together with the use of a single-entry turbine, increases overall turbine efficiency.

Experimental investigation of the sequential method has shown an important improvement in engine performance. It is believed that savings resulting from lower fuel consumption can comfortably pay the additional cost of the sequential turbocharging system. The sequential method uses conventional production units. The lower exhaust gas temperature and good matching increase the reliability of the TCs by lowering the thermal load. It does not appear that the gas flow control system need be any more complex than in a system with a variable geometry turbine or a wastegate.

Diesel Emissions[2]

Much attention has been given in recent years to reducing the emissions from heavy-duty, diesel-powered vehicles. Stringent NO_x and particulate emissions standards have been established in the United States. The technologies considered, in order of their likely successful application, include (1) diesel fuel modifications, (2) trap-oxidizers, (3) conversion to methanol fuel, (4) particle agglomerators, (5) fumigation with liquefied petroleum gas (LPG), (6) vertical exhausts, (7) special fuel additives, and (8) high-altitude adjustments/kits. Proposed (1991) standards specify: (particulate matter) 0.25 grams and NO_x 5.0 grams per brake horsepower per hour. These standards will require the use of trap-oxidizers or similarly effective techniques. Since the lifetime of these large vehicles generally exceeds ten years, full effects of the changes will not have been realized until after the year 2000.

Fuel Quality Improvements. Diesel fuel quality affects emissions through its effects on the combustion process. Most indices of fuel quality have deteriorated during recent years and are expected to continue to do so. The quality indices of greatest concern are the sulfur and aromatic hydrocarbon contents of the fuel. Back-end volatility was previously considered important, but this has been found untrue for the range permitted in diesel fuel. Cetane numbers are closely related to aromatic content.

The ASTM (American Society for Testing and Materials) standard for diesel #2 fuel allows up to 0.5% S by weight. The national average is about 0.29%, while in the Rocky Mountain region, the average is 0.37% S. The requirement for a cetane number of 40 or more indirectly limits aromatics which average about 29% for the United States.

It is estimated that about 98% of the sulfur is exhausted as SO_2, the balance forming sulfuric acid (H_2SO_4) and various metal sulfates which exit as particulates. These typically make up 5–10% of total direct diesel particulate emissions. Much of the gaseous SO_2 reacts in the atmosphere to form sulfate particles; perhaps 1.2 gram of particles per gram of SO_2 emitted. For a typical heavy-duty engine burning 0.4% S fuel, this amounts to about 1.75 gram per brake horsepower hour. Direct particulate emissions from such an engine typically range 0.6–0.8 gram per brake horsepower per hour.

Sulfur in diesel fuel is one of the major causes of engine wear due to the corrosive effect of H_2SO_4 in the blowby and exhaust gases. One source estimates that a reduction in S from the nationwide average of 0.3% to 0.05% would increase engine life and time between overhauls by about 30%. Oil life would be significantly extended, providing savings. NO_x, hydrocarbon (HC), and particulate emissions are all significantly increased during transient conditions in turbocharged engines. Reducing aromatics from the national average of 29% to 17% by volume would reduce the carbonaceous particulate emissions by about 30% (based on limited data). It would also raise the average cetane number to about 50–55 at this lower level, thus improving cold-start performance and HC, NO_x, and noise emissions.

It has been estimated that dropping S and aromatics to the recommended levels would cost about 1.5 cents per gallon of fuel. An upper bound of 3.0 cents per gallon can be anticipated at some future date. However, savings in maintenance and engine life, not to mention environmental improvement, would offset this increase in fuel cost. Some authorities suggest that implementation of the foregoing measures would have immediate positive effects and a negative social cost.

Trap-Oxidizers. An emission control technique, trap-oxidizers are quite efficient but relatively costly. Thus they are especially well-suited to installation on high-mileage, high-public exposure vehicles, such as transit and school buses and rubbish collection and other kinds of municipal vehicles. Trap-oxidizers appear to be the only technology with sufficient promise to meet the aforementioned Federal as well as California particulate standards. In addition to use on new vehicles, older, existing vehicles can be retrofitted with them.

Filter development has been fairly straightforward, but regeneration can be a problem if cracking or melting of the substrate is to be avoided. Many regeneration systems have been developed for ceramic monolith traps. See Fig. 3. The system most suited to retrofit applications is the use of catalytic fuel additives to promote regeneration. These additives lower ignition temperatures of the collected particles to within the engine's normal operating range. This passive regeneration approach avoids any need for complex sensors or controllers. In some cases, an even simpler "active" regeneration system would be feasible with the Corning trap. It would consist of regular full-power operation for several minutes (possibly with some intake or exhaust throttling) to raise the exhaust temperature above the particulates' ignition point. This approach would require active participation of the drive and thus would appear to be applicable mainly to controlled fleets, such as transit operations.

Another promising technology is the Johnson-Matthey trap, which consists of a hollow cylinder of stainless steel wire mesh, covered with

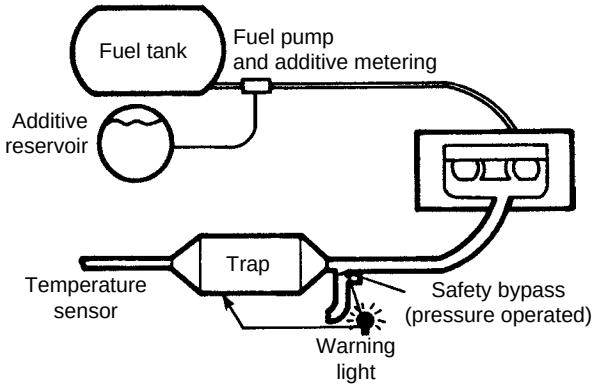

Fig. 3. Ceramic monolith trap-oxidizer with fuel-additive self-regeneration.

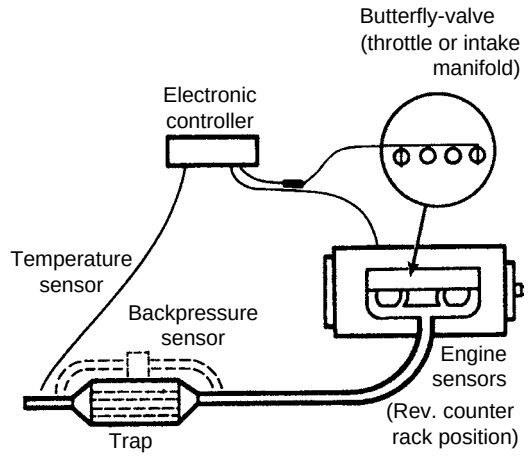

Fig. 4. Catalyzed wire-mesh trap-oxidizer and regeneration system. Electronics and throttle valve required only for light-duty cycles.

a washcoat containing precious-metal catalyst. This catalyst lowers the particulates' ignition temperature to the point of ensuring regeneration in moderate-to-heavy duty cycles. See Fig. 4. Vehicles having lighter duty cycles would call for a positive regeneration system. The catalyst promotes oxidation of SO_2 to sulfuric acid and other particulate sulfates. If used with low-sulfur fuels, the life of the trap would be extended and less expensive catalysts could be used.

Methanol Engines. Although methanol and ethanol are excellent fuels for Otto-cycle engines because of their resistance to self-ignition, this characteristics makes them poor fuels for conventional diesel-cycle engines and calls for spark ignition, glow plugs, or dual-fueling with diesel fuel to ensure proper ignition. Even with these shortcomings, there are potential advantages of the alcohols because of their energy content and low emissions. This has led to the development several diesel or diesel-like engines — designed mainly for the use of methanol.

Partial substitution for diesel fuel can be achieved by use of alcohol/diesel solutions and emulsions, or by fumigation of the intake air with alcohol, although neither option allows substitution for more than about 25–30% of the diesel fuel. Dual injection of both fuels into the combustion chamber is another approach. This can allow substitution of up to 80% of the diesel fuel by alcohol. Spark or glow plug ignition permits complete substitution.

Substantial worldwide attention has been directed mainly to methanol-fueled engines for transit-bus applications. However, before such fuels can be used widely, considerable additional reliability and durability testing must be conducted. Results from fleets operating in Berlin, Seattle, and Southern California will furnish important inputs. Since bus engine overhauls occur typically every 4–6 years, the demonstration of durability will require a considerable time span. Normal durability of present heavy-duty diesel engines is typically 200,000 to 400,000 miles between major overhauls. It is considered unlikely that newly developed methanol engines will do as well immediately after their introduction. There have been early signs indicating that such engines may exhibit premature wear and corrosion in smaller sizes, but that larger engines operating at higher load factors may do better. It is estimated that commercially built methanol engines will likely add costs ranging from $5,000 to $10,000 per unit over the next decade and that the cost of methanol fuel will be somewhat higher than regular diesel fuel. A major ingredient pertaining to the viability of this option is that of building a widespread methanol fuel production and distribution program.

Particle Agglomerators. The foregoing measures pertaining to diesel emissions are desirable because they can reduce the mass of emitted particles per mile of vehicle use. In the particle agglomerator approach, the target is not reduction of mass created, but rather conversion of particulate material emissions into somewhat less noxious forms. The agglomerator would aggregate fine soot particles (nearly all less than 10 micrometers in diameter) to produce much coarser particles. These large particle entities would have less effect on visibility and soiling, less residence time in the atmosphere, and would be filterable by the human nasal system. See Fig. 5.

In another system, an electrostatic collector is combined with a cyclone collector. The system has demonstrated particulate mass collection efficiency as high as 58%. The system provides the same muffling capability while occupying the space normally used by one and one-half mufflers. Thus a retrofit could be configured as a muffler. The design is still under development. See Fig. 6.

LPG Fumigation. Diesel engines can be made to burn a wide variety of combustible gases, vapors, and even liquids by mixing these materials with the intake air before it is drawn into the cylinder. A charge is drawn into the cylinder and compressed with the intake air, then ignited by combustion of the diesel fuel injected in a normal manner. This process is termed fumigation when the primary fuel is diesel, or dual-fueling when most of the energy comes from the alternative fuel. A number of studies have shown that fumigation with LPG and other hydrocarbons can drastically reduce visible smoke emissions from diesel engines at high loads, thus increasing smoke-limited power. Such reductions cannot be translated directly into reduction in average particulate emissions, since normal vehicles spend comparatively little time operating at maximum power. A number of technical problems remain.

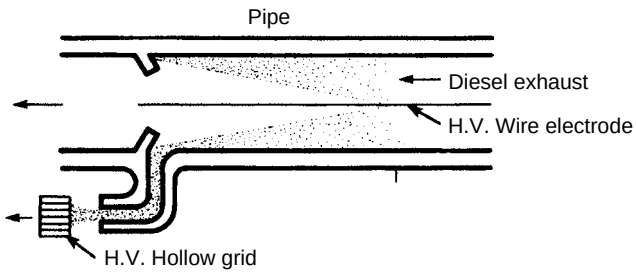

Fig. 5. Electrostatic precipitator for diesel particulates agglomeration.

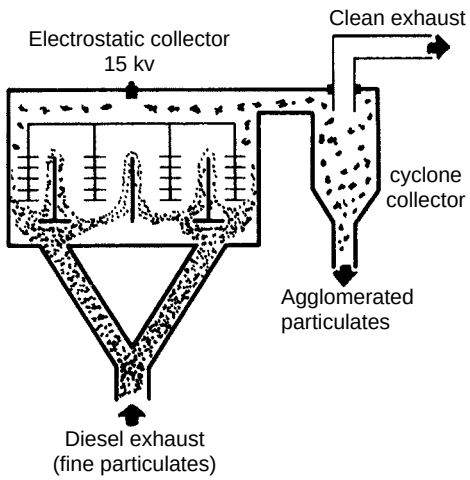

Fig. 6. Combined electrostatic collector-cyclone separation device.

Vertical Exhaust. Choice of vertical or horizontal exhaust pipes does not affect overall pollutant emissions, but it can significantly alter their local concentrations. Vertical exhausts reduce both chronic and acute health problems to some degree.

DIE SINKING. The process of cutting a recess or cavity in a die for drop forging, press working, or plastic molding.

DIET. Because of the importance and exceptional complexity of the topic, the human diet has been controversial; with research studies (frequently incomplete and inconclusive); and with scores of packaged food suppliers seizing opportunities in the marketplace to make claims when findings are favorable and disclaimers when negative facts are presented; and with scores of specialized publications and the news media in general seeking every opportunity to cover a "new" diet topic for their audiences. These kinds of activities tend to eclipse the really excellent work accomplished on a continuing basis by professionals in the field and to make recommendations of healthy diets as contrasted with diet fads, which, without scientific proof, can be dangerous. Over the past several years, the public in many countries has learned to expect reliable diet and other health information from government sources. In the United States, this has fallen mainly to the U.S. Department of Agriculture and the U.S. Department of Health and Human Services. Indeed, the nutritional scientists at the governmental level carry a heavy responsibility in preparing dietary guidelines that, on the one hand, are safe but too general to be of great specific value and, on the other hand, backing up claims that are not fully proven "truths." As a result the most recent (1990) "Food Guide Pyramid," released by government sources, has not received universal acceptance, but generally is regarded by professionals as a good step in the right direction for educating the public. See Fig. 1.

U.S. Department of Agriculture (USDA) Survey

Detailed statistics on food consumption usually are several years late in their publication. Thus, the following observations, published during the early 1990s, reflect actual figures as of 1988. Following are a few dietary highlights:

Protein. In 1988, animal foods contributed about two-thirds of all protein available in the U.S. food supply.

Calcium. Milk and milk products are the major source of calcium in the food supply, accounting for three-fourths in 1988. Adequate calcium is essential for developing teeth and bones, muscle contraction, and normal blood clotting. Research indicates that adequate calcium intake in childhood and early adulthood may reduce the risk of bone fractures late in life. However, recent USDA consumption surveys indicate that the calcium intake of many Americans, especially women, is below the Recommended Dietary Allowance (RDA) as established by the U.S. National Academy of Sciences.

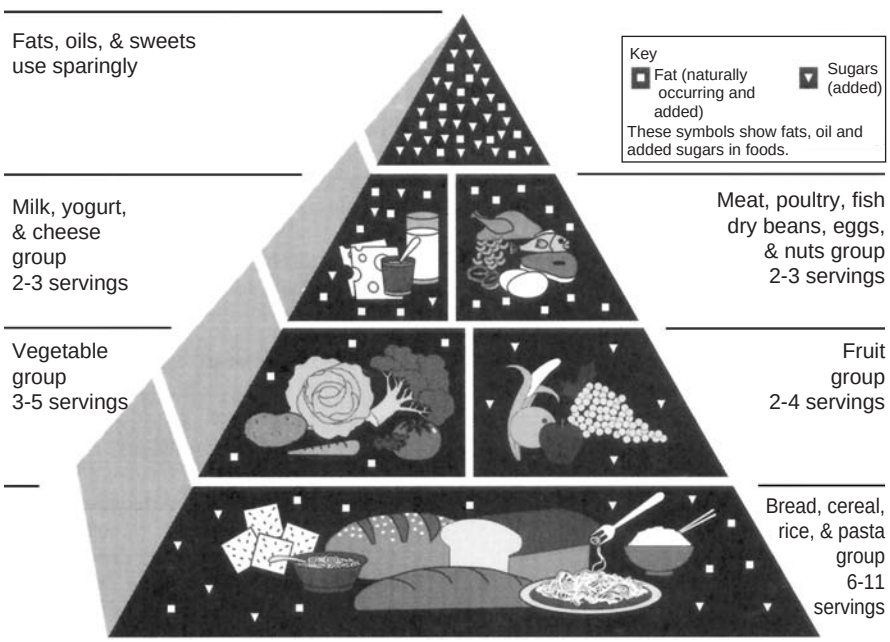

Fig. 1. Food Guide Pyramid. A Guide to Daily Food Choices for Healthy Americans over the Age of Two Years. *General Recommendations*: (1) Eat a variety of foods, (2) Maintain healthy weight, (3) Choose a diet low in fat, saturated fat and cholesterol, (4) Choose a diet with plenty of vegetables, fruits, and grain products, (5) Use sugars only in moderation, (6) Use salt and sodium only in moderation, and (6) If you drink alcoholic beverages, do so in moderation. (*U.S. Dept. of Agriculture and U.S. Dept. of Health and Human Services*.)

Iron (In Biological Systems). Meat, poultry, fish, and eggs contributed 25% of the iron in the food supply in 1988, second only to grains. Since only about 5 to 15% of iron consumed is absorbed and used by the body, animal products are considered an important source. Meat, poultry, and fish contain heme iron, a type that is more absorbable than the type in plant products, or the iron added through enrichment. Iron-deficiency anemia is believed to be the most prevalent nutritional deficiency in the United States. Infants, young children, adolescents, and women of childbearing age are most at risk. In 1985, less than half of young children and less than one-quarter of women of childbearing age consumed their RDA of iron.

Other Minerals. Animal foods were the largest contributors of zinc and phosphorus, providing two-thirds of the supply of each. The meat, poultry, fish, and egg group provided the largest share of zinc, 50%. Dairy products and the meat, poultry, fish, and egg group each provided a third of the phosphorus. Animal foods also contributed substantial proportions of potassium (40%), magnesium (35%), and copper (22%) in the food supply.

Vitamins. Animal products are important sources of many vitamins. Except for small amounts added to cereals, animal foods are the only source of vitamin B-12 in the food supply. Animal foods also are the primary source of riboflavin. In 1988, milk and milk products accounted for a third of the available riboflavin, and the meat, poultry, fish, and egg group provided another 29%.

The meat, poultry, fish, and egg group is the leading source of vitamin B-6 and niacin, providing 43% of vitamin B-6 and 45% of niacin in 1988. This group ranks second as a source of vitamin A and thiamin, accounting for about a fourth of the total supply of each in 1988.

Animal fats add little to the amount of essential nutrients available in the food supply. The only significant contribution is the small amount (3%) of vitamin A provided by butter.

See separate entries in this encyclopedia for further detail pertaining to each of the principal vitamins.

Fat and Cholesterol. Animal products contributed about half of the total dietary fat in the food supply in 1988. Meat, poultry, fish, and eggs provided 34% of total fat, milk and milk products contributed 12%, and animal fats 7%. The remainder came from plant products, primarily vegetable fats and oils.

Saturated fats are found primarily in high-fat animal products, hydrogenated vegetable fats, and some vegetable oils, such as coconut and palm oil. In 1988, animal products contributed slightly less than three-fourths of saturated fats in the food supply. The meat, poultry, fish, and egg group provided the largest share, 42%. Milk and milk products accounted for 20%, and animal fats 11%. Most of the remainder came from vegetable fats and oils.

Cholesterol is found only in animal foods. Meat, poultry, fish, and eggs contributed 80% of the cholesterol in the food supply in 1988. Eggs, an especially rich source of cholesterol, contributed 33%, and meats provided 31%. (These figures for eggs reflect a reduction in cholesterol value for eggs that is 22% lower than former estimates.) Milk and milk products accounted for 15%, and animal fats contributed 3%.

Diet and Disease

Cholesterol and Fats (Lipids). The literature on nutrition for several years has targeted heavily on the role of cholesterol as a causative factor in connection with several major dysfunctions of the heart and circulatory system. Discussions of cholesterol are accompanied by reference to the metabolism of fats and lipids. Various aspects of this topic are described in several articles in this encyclopedia. See also **Arteries and Veins (Vascular System)**; **Cholesterol**; **Heart and Circulatory System (Physiology)**; **Hypertension (High Blood Pressure)**; **Lipids**; and **Vegetable Oils (Edible)**.

Cholesterol, both the "bad" and the "good," are associated with the metabolism of fats and oils that are contained in our diet. It will be recalled from Fig. 1 that the U.S. Department of Agriculture and the Department of Health and Human Services place fats and oils, along with sweets, at the peak of the diet choice triangle, suggesting that these substances be used sparingly.

Until researchers develop an understanding of how these substances react chemically at the molecular level (along the lines of a research trend just commencing in connection with cancer research), health professionals and consumers will depend largely upon guidance that comes out of the statistical findings of group studies and diet experimentation.

Reference is made to a paper by J.E. Manson (Brigham and Women's Hospital and a team from that institution and the Harvard Medical School), sponsored by the National Institutes of Health (U.S.); the report observes, "Basic research and evidence from observational studies and clinical trials have shown such a consistent positive relation between the serum cholesterol level and the risk of heart disease that the association has been judged to be causal by the National Heart, Lung, and Blood Institute. Recent overviews have indicated that a 1 percent reduction in a person's total serum cholesterol level yields a 2 to 3 percent reduction in the risk of coronary disease. Furthermore, there appears to be no evidence of a threshold effect. In a recent prospective study of cholesterol and heart disease among subjects with relatively low total cholesterol levels (160 10 190 mg per deciliter [4.1 to 4.9 mmol per liter]), 10 percent increases in the base-line cholesterol level were associated with 21 percent increases in the risk of death from coronary heart disease. These relations are present in the elderly as well as the young, in women, and in all racial groups. Dietary, environmental, and genetic factors all have important roles in determining blood levels of cholesterol as well as rates of coronary disease, as has been observed in migrant studies."

The report further observes, "The estimated reduction in the risk of myocardial infarction is 2 to 3 percent for each 1 percent reduction in the serum cholesterol level. On average, 10 percent reductions in the cholesterol level are achieved with dietary therapy and 20 percent reductions with drug therapy."

To indicate that much additional study is required regarding plasma cholesterol, researcher H.N. Ginsberg, and a Columbis University College of Physicians and Surgeons team of researchers, have observed, "Although the relation between dietary intake of fatty acid and plasma cholesterol levels have been studied for more than 20 years, the most effective dietary approach for reducing plasma concentrations of total cholesterol while achieving an optimal relation between plasma levels of low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol remains controversial. There are limited data on the ability of diets similar in both fat and cholesterol content to the American Heart Association "Step 1" diet to reduce plasma levels of total and LDL cholesterol in healthy, noninstitutionalized persons who follow practical diets for long periods. In addition, the relative efficacy of reducing the total fat intake by reducing only the intake of saturated fat as compared with replacing the saturated fat with monounsaturated fat or polyunsaturated fat is unclear."

Thus, based upon empirical rather than scientifically proved facts, the topic of fat substitution has risen during the last few years and has offered at least marketing opportunities to a number of products. Some recent studies have stressed the role of monounsaturated fatty acids in reducing saturated-fat intake and thus lowering the serum level of the atherogenic low-density lipoprotein (LDL) cholesterol. Oleic acid is an example. This acid has a cis configuration (carbon moieties lie on same side in a structural formula). There are, however, *trans* fatty acids in which the carbon moieties are situated on the same side. Obviously, at the molecular level, this is a major difference and of the type that must be taken into consideration in connection with diet therapy for alleviating a cholesterol problem. These latter trans-fatty acids are found in specific kinds of margarines, margarine-based products, shortenings, and fats used for frying. Trans-fatty acids also are formed when vegetable and marine oils, which are rich in polyunsaturated fatty acids, are hardened by the widely used process of hydrogenation for producing fats that have the qualities of firmness and plasticity desired by both food product manufacturers and consumers. It has been estimated that from 6 to 8% of total daily fat consumption in the United States is of trans-fatty acids. The intake is much larger by persons who have dietary preferences for these fats. The claims made for trans-fatty acids as a replacement for saturated fatty acids may be grossly overstated, as for example, margarine versus butter.

A finding along these lines has been reported by R.F. Mensink and M.B. Katan.* The conclusions: "The effect of trans fatty acids on the serum lipoprotein profile is at least as unfavorable as that of the cholesterol-raising

* Study sponsored by Netherlands Nutrition Foundation, the Netherlands Ministry of Welfare, Public Health, and Cultural Affairs, and the Commission of the European Communities.

saturated fatty acids, because they not only raise LDL cholesterol levels but also lower HDL cholesterol levels." See reference listed.

An excellent summary of the cholesterol problem is given by W. Willett (Harvard School of Public Health) and F.M. Sacks (Harvard Medical School): "In the absence of fully satisfactory data directly relating dietary factors to the risk of coronary heart disease in humans, a surrogate end point, the serum cholesterol level, has been used to predict the effects of diet. The fundamental supposition is that because high serum levels of cholesterol, cause coronary heart disease, the effect of a dietary risk of the disease can be predicted by its effect on LDL cholesterol. However, the complexity of the plasma lipoprotein system limits the validity of considering only one of its components, because different fractions are incompletely understood and even have opposite effects, as do LDL and HDL (high-density lipoprotein) cholesterol. Moreover, dietary factors may operate through enhancing or competing mechanisms, such as platelet aggregability, endolethial integrity, and oxidation of lipids."

What are the effective alternative sources of calories? Among practical options are polyunsaturated fat, monounsaturated fat, and complex or simple carbohydrates. In terms of polyunsaturated fat, extensive studies of laboratory animals have raised the fear of prolonged usage as increasing the risk of some cancers. Regarding the other alternatives, Willett and Sacks comment, "Replacing land-mammal fat with carbohydrate, which implies a major reduction in total fat intake, has been advocated by many groups. This dietary maneuver, however, effectively lowers levels of HDL cholesterol, although usually not as much as levels of LDL cholesterol. Monounsaturated fats such as olive oil may be an equally good or superior replacement source of calories, as judged by the effects on blood lipids and the extraordinarily low rates of coronary heart disease and most cancers among Greeks. A reasonable policy would seem to admit uncertainty about the most desirable replacement sources of energy for land-mammal fat, allowing us to hedge our bets with a mix of complex carbohydrates and vegetable oils containing mainly monounsaturated and polyunsaturated fatty acids. A narrow focus on minimizing total fat intake does not currently appear to be justified. The uncertainty also highlights the need for better epidemiologic data to complement existing metabolic information."

For the interested scholar, reading the Willett-Sacks paper in its entirety is suggested.

Role of Fiber in Diet. The value of fiber in the human diet was mentioned as early as 400 B.C. by Hippocrates, who identified bran as a laxative. Over the years, dietary fiber has been variously defined:

- *Crude fiber is the residue remaining after treatment (of a foodstuff) with hot sulfuric acid, alkali, and alcohol. It consists primarily of cellulose, lignin, and trace amounts of other polysaccharides*. (Association of Official Analytical Chemists.)
- *Mostly celluloses and lignin and lignin material, varying in different plants according to type and age. Basically, it passes through the small intestine undigested by our enzymes. A kind of natural and necessary laxative*. (D.P. Burkitt and H. Trowell, 1975).
- *That part of plant material in the diet that is resistant to digestion by the secretions of the human gastrointestinal tract, consisting of variable proportions of complex carbohydrates, such as celluloses, hemicelluloses, pentosans, and uronic acids, as well as lignin.* (A revised 1986 definition.)
- *Plant material which is resistant to hydrolysis by the endogenous enzymes of the mammalian digestive tract*. (Institute of Food Technologists' Expert Panel on Food Safety and Nutrition, 1989.)

Comparatively recent interest in dietary fiber was initiated D.P. Burkitt and H. Trowell in the early 1970s. Burkitt, a British medical researcher and surgeon had observed that rural Africans, whose diets are high in fiber-containing foods, had a lower incidence of a number of diseases, including appendicitis, hemorrhoids, diverticular disease, cardiovascular disease, and cancer of the colon than those persons who live in the western, developed nations. Diets in the latter countries traditionally have been comparatively low in fiber content.

Detailed research soon indicated that, as related to health, various fibers differed considerably in their effectiveness. Of course, as mentioned in connection with the cholesterol problem, data of an epidemiological nature pertaining to fibers also must be reviewed carefully against the underlying complexities of the data. Such studies do not conclusively prove a cause-and-effect relationship.

The term *crude fiber* as traditionally used may represent as little as one-seventh of the total dietary fiber of a given food. It is possible that the term fiber in itself may be somewhat misleading, inasmuch as all components of presently regarded "dietary fiber" are not fibrous in the usual physical sense, while, at the same time, some foods that contain recognizable fibers, such as muscle meats, do not yield undigestible residue.

The Institute of Food Technologists (IFT) identifies five principal categories of dietary fibers:

Cellulose — A linear polymer of glucose with beta 1–4 links, it is the main structural component of plant cell walls. It is essentially insoluble in water. (The term "noncellulosic polysaccharides" [NCP] has been suggested as a descriptive term for the broad range of polymers classified as pectic substances, beta glucans, and hemicelluloses.)

Beta-Glucans — These are glucose polymers that contain both beta 1–3 links as well as beta 1–4 links in various proportions, depending on source. This makes the molecule less linear than cellulose and more soluble in water. Cereals rich in beta-glucans include barley and oats.

Pectins — These are pectic substances composed mainly of rhamnogalactouronans (D-galacturonic acid and rhamnose), and they contain other carbohydrate moieties as side chains. Water-soluble pectins and insoluble protopectins are found as part of the cell walls and middle lamallae. Modifications of pectic substances that alter their solubility or gelling properties are likely to influence the physiological response to pectin as a source of fiber. Many fruits are good sources of pectic substances. See also **Pectins**.

Hemicelluloses — These compose a heterogeneous group of polysaccharides that contain a variety of different sugars in the polymeric backbone and side chains. They can be classified by the monosaccharide composition of the backbone. Examples of polysaccharides in this group include arabinoxylans (xylose backbone with arabinose side chain), galactomannans, and xyloglucans. Hemicelluloses are soluble in dilute alkali.

Lignin — This is a highly complex nonpolysaccharide polymer that contains phenylpropane units derived from phenolics, such as sinapyl, coniferyl, cinnamyl, and *P*-coumary alcohols. Lignins are insoluble and resistant to human digestion. See also **Lignin**.

Other Fibrous Components of Foods — Although they do not conform fully with the prior definitions of fibers, some substances elicit physiological responses to diets rich in fiber-containing foods. Examples are phenoloic compounds, phytic acid, digestive enzyme inhibitors, Maillard compounds, and starch that is resistant to digestion.

The structures of some dietary fiber compounds are shown in Fig. 2. The chemical classification of dietary fiber is given in Table 1. The dietary fiber content of selected foods is given in Table 2.

The IFT describes dietary fibers, in terms of their effectiveness and as a guide to research projects, as (1) their *chemical-physical properties*, and (2) their *physiological* effects.

Chemical-Physical Properties. The physiological effects of fibers in the diet generally result from the following properties:

Microbial Degradation of Polysaccharides — Dietary fiber cannot be enzymatically degraded in the mammalian small intestine. The fiber, however, is fermentable to varying degrees by the microflora that occur in the large intestine. The degree of degradation varies among the polysaccharides and is related to water-holding capacity and the polysaccharide structure of the fiber. Pectins, mucilages, and gums generally are completely degraded, whereas cellulose is only broken down partially. Researchers have found, for example, that short-chain fatty acids produced during microbial metabolism can influence physiological responses to the fiber — cells in the colon may use the short-chain fatty acids as a source of energy, and absorption of these acids may influence hepatic (liver) metabolism of lipids and glucose. The fermentation process may lower the acidity (pH) of the large intestine and affect the activity of microbial enzymes. Microbial cells can account for a significant portion of fecal weight and thus contribute to fecal bulk.

Water-Holding Capacity — Pectins, mucilages and, to a lesser extent, hemicelluloses have a high water-holding capacity. Hydration of the fibers results in the formation of a gel matrix. This may raise the viscosity of gastrointestinal contents and thus slow gastric emptying and the diffusion and absorption of nutrients. Typically, a higher water-holding capacity is associated with greater fermentability of the fiber source.

Adsorption of Organic Molecules — In-vitro research has shown that lignin is an effective bile acid absorbent. Pectin and other acidic polysaccharides also sequester bile acids. By contrast, cellulose has little effect

on bile-acid binding. Some researchers have related the ability to increase fecal bile acid excretion with the plasma cholesterol lowering effect of certain fiber sources. Among the fibers found to be effective are oat bran, guar gum, and pectin. Although the ability of some fibers to bind toxic substances has not been researched fully, some investigators have proposed this as a protective mechanism in connection with gastrointestinal cancers.

Cation Exchange Capacity—It has been observed that the reduced mineral availability and electrolyte absorption associated with some high-fiber diets arise because of the binding of minerals and electrolytes, which leads to increased fecal excretion of minerals and electrolytes. The number of free carboxyl groups on the sugar residues and the uronic acid content of polysaccharides are related to the cation exchange properties of fibers.

Particles Size—It has been suggested that grinding dietary fibers to a smaller particle size may influence their physiological effects. This is an area that requires considerably further study.

Physiological Properties. The aforementioned chemical-physical properties of dietary fibers are relatively easy to determine in the laboratory (*in-vitro*). However, the translation of these properties into terms of their action within the human gastrointestinal system poses long-term studies and essentially returns the research to a statistical and empirical basis. Nevertheless, there are a few strategic measurements that can be made without compromising cooperating subjects. These include, for example, the effect of various fibers on fecal weight and transit time.

Current, but not fully reaffirmed findings of the effects of dietary fibers on a few important human dysfunctions are given in the following paragraphs.

Constipation. The value of fiber in increasing water content of feces has been mentioned. Fiber tends to effect a transit time in the gastrointestinal tract which is intermediate between being too rapid (diarrhea) and too slow (constipation). Some authorities theorize that the increased volume and softness of the stools, by reducing straining during defecation, is a factor in preventing hemorrhoids, varicose veins, and stroke.

Diverticulosis. Diverticula are outpouchings that develop in weak areas in the bowel wall. If they are numerous and become inflamed, diverticulitis is the result. Accompanying the condition quite frequently is pain in the lower left side, an alternating diarrhea and constipation, and flatulence. Diverticulitis was essentially unknown prior to the turn of the century, but the incidence of the disorder has increased markedly in industrialized countries. In western countries, as of the early 1990s, it was estimated that from one-fourth to one-third of the population of older persons may have suffered some or all of the symptoms of diverticulitis. Prior to the current recognized treatment with high-fiber diet, it was treated with a low-residue diet, presuming that such a diet would permit healing and cause less irritation to the bowel. See also **Diverticulosis and Diverticulitis**.

Cardiovascular Diseases. As previously mentioned, a high-fiber diet may lower the blood cholesterol levels by reducing transit time through the gastrointestinal tract. People on certain high-fiber diets excrete more bile acids, sterols, and fat, implying that the fiber compounds "bind" bile acids and thereby prevent absorption of cholesterol and fat and also the reabsorption of bile acid derived from the body's cholesterol. High serum cholesterol levels have been identified as one of the risk factors in atherosclerosis, although there is disagreement as to whether the actual risk can be reduced by lowering cholesterol levels by means of diet or drugs. Complicating any resolution of the role of dietary fiber in cardiovascular disease are the inconsistent effects produced by dietary fiber from different foods.

Cancer. The hypothesis relating dietary fiber to colon cancer presumes that the slow movement of the feces that occurs with a low-fiber diet allows more time for any carcinogens present in the colon to initiate cancer. Also, the extra water, bile acids, salts, and fat bound by added fibers are assumed to act as solvents to remove a wide variety of chemical factors which may be carcinogenic. A high-fiber diet also may alter the type and number of microorganisms in the colon, which produce compounds convertible to carcinogens. Theories based essentially upon correlations of various population characteristics can, of course, be misleading. As just one example, the incidence of colon cancer in different countries and cultures correlates much better with the consumption of fat in the diet than it does

TABLE 2. DIETARY FIBER CONTENT OF SELECTED FOODS (Grams per 100 grams Edible Portion)

	Moisture	TDF*
Bakery Products		
Bagels, plain	31.6	2.1
Breads		
Bran	37.7	8.5
Cracked wheat	35.9	5.3
Mixed-grain	38.2	6.3

with the consumption of fiber. As of the early 1990s, there has been no proven relationship between bowel transit times and the incidence of colon cancer. Also, there is no proof that constipation leads to cancer, and none that dietary fiber per se has a definable effect on the intestinal flora in humans.

Excessive Fiber in Diet. With emphasis upon the probable beneficial effects of dietary fiber, the question of the consequences of fiber overdose so to speak is rightfully brought forward. Much less research on this point has been conducted. It has been suggested that too much pectin may cause decreased vitamin B_{12} absorption. This would be an important concern for certain types of vegetarians whose diets are already low in that vitamin and high in fiber. There may also be a significant loss of minerals, particularly zinc, iron, calcium, copper, and magnesium, due to binding of these minerals by phytic acid, present in certain plant-based foods. The high-fiber diets of Africa and India, for example, are associated with a high incidence of such mineral deficiencies and kidney stones, especially in areas where rice is the major calorie source. The rate of stomach cancer in some of these areas is high, which should lead to cautious interpretation of epidemiological studies. Also, fiber, by its sheer bulk, may reduce the total amount of food consumed, thereby resulting in the deficiency of certain nutrients and, possibly in extreme cases, to reducing calories in areas where malnutrition already exists.

Diet and Hypertension

As of the early 1990s, intensive research efforts continued toward learning more about dietary calcium and the general relationship between nutrition and essential hypertension. See also **Hypertension (High Blood Pressure)**. One hypothesis proposes that dietary calcium has an inductive effect on vascular smooth muscle, which corrects an underlying defect in cellular calcium metabolism. Considerable research has been conducted in which spontaneously hypertensive rats (SHR) are used. Calcium is not the only nutrient to be implicated in blood-pressure regulation. Traditionally, excessive dietary sodium most often has been attributed as an underlying cause. Some researchers are studying what may be a synergistic action between dietary calcium and sodium.

Although there is substantial epidemiological evidence that links sodium to blood pressure, controversy concerning the role of this element in human hypertension remains. Interventional studies indicate that some, but not all normotensive individuals have a rise in blood pressure with massive sodium loading and that a similar variability exists in the blood pressure response to sodium restriction in normotensive as well as hypertensive humans. Thus, not all individuals will have their blood pressure increased by a liberal sodium intake, nor will all of those persons with elevated blood pressure demonstrate a decrease in blood pressure with sodium depletion. These observations have prompted new avenues of research.

The effect of any one nutrient on blood pressure may depend more on its interactions with other dietary constituents than on its level in the diet. Experimental evidence emphasizing a single dietary component has several shortcomings. When one dietary component is modified, the relative contribution of other components may change, thus causing the composition of the whole diet to attenuate or exaggerate the effect of a specific nutrient on blood pressure as well as any other conditions which may be under study. A further difficulty encountered when studying the role of dietary factors in hypertension is the individual variability in response to dietary adjustment. Although it is very difficult to study the influence of nutrient interactions on regulation of blood pressure, the fact that individuals consume complex diets necessitates this approach. Several dietary interactions associated with controlling hypertension have been found.

Calcium and Magnesium. Studies have been made of dietary interactions of Ca and Mg in SHR and normotensive rats. Excessive consumption of calcium over magnesium will seriously alter the dietary Ca/Mg ratios. Although it is unlikely that humans would consume a diet containing calcium/magnesium ratios as high as those used in studies of rats, it was noted that rats fed high ratios exhibited Mg deficiency signs after just 3 weeks on the diet. In addition, absorption of trace minerals can be modified. Thus, it may be well to advise those individuals who do not consume dairy products to select Ca supplements that also contain Mg and a balance of trace elements.

Sodium and Potassium. Some evidence suggests that simultaneously lowering dietary salt while increasing dietary potassium may be beneficial in regulating and preventing hypertension. A reduced dietary sodium/potassium ratio may reduce blood pressure by reducing extracellular fluid volume, since increased dietary potassium is associated with increased sodium excretion. Indeed, a large weight loss is frequently reported when a low-sodium/high-potassium dietary intervention is imposed. Other possible mechanisms of action include central or peripheral nervous system effects, altered renin-angiotensin-aldosterone axis activity, alterations in peripheral resistance, and antagonism of the effect of natriuretic hormone.

Sodium and Calcium. Evidence of a dietary Na/Ca interaction in regulating hypertension is emerging. In a controlled, crossover human study, an increase in urinary excretion of Ca accompanied an increase in Na intake. Some authorities now believe that sodium is important for intestinal absorption of calcium and for the membrane-stabilizing effects of calcium. Another hypothesis suggests that excessive Na consumption may overload the renal capacity to excrete Na, resulting in fluid retention and this, in turn, is thought to promote secretion of natriuretic hormone which inhibits the sodium pumps of the kidney, thus promoting sodium and fluid excretion.

Salt and Fat. Polyunsaturated fat sources have been shown to counteract sodium-induced hypertension in rats. Polyunsaturated fats are a source of linoleic acid, which may be a precursor of prostaglandins which increase sodium excretion and contribute to the regulation of arterial blood pressure. To date, controlled studies examining dietary salt and fat interactions in hypertension of humans have yet to appear. It still has not been established that there is a salt/fat relationship; blood pressure may respond to the sum of their individual contributions.

Some researchers conclude that the involvement of nutrient interactions in hypertension to date have largely been explored in animal models. Based upon current epidemiological data, excessive caloric intake may be the single most important dietary factor in the pathogenesis of hypertension. A prudent diet to minimize risk of hypertension might include the following: (1) control body weight; (2) limit intake of salt; (3) ensure adequate intakes of calcium, magnesium, and potassium; (4) increase the ratio of polyunsaturated to saturated fat; and (5) moderate the consumption of alcohol and caffeine — all factors that have been established by way of practical experience but against a backdrop of relatively poor understanding of the fundamentals over the past several years.

Food Allergies and Sensitivities

A *food allergy* may be defined as an adverse reaction to a food or food component, frequently a protein, that involves the individual's *immune system*, i.e., ingestion of a specific food substance will trigger an immunological reaction. For clarity, the term allergy should be used exclusively in connection with immune system reactions. Examples of common foods which cause allergic reactions, experienced on an individualistic and not mass basis, include milk; eggs; tree nuts; crustaceans, such as shrimp, crab, lobster; shellfish, such as clam, oyster, and scallop; legumes, such as peanut (groundnut) and soybean; wheat; and fish. Where allergic reactions are relatively common, the term allergenic food may be used.

Type I Allergies. Also known as *food anaphylaxis*, Type I allergy refers to allergic reactions to foreign protein molecules. The mechanisms of allergic reactions are described in article on **Immune System and Immunology**.

Type I reactions usually occur within a few minutes to several hours after ingestion of an offending food substance. The observed symptoms result from the release of pharmacologically active substances, known as *mediators*, such as histamines. Exercise-induced food anaphylaxis is a subset of food anaphylaxis that involves reactions that occur only when the specific food is ingested just before or just after exercise. A number of exercise-induced anaphylaxis situations are not food related.

Type II and III allergies seldom relate to foods.

Type IV Allergies. Sometimes called *cellular hypersensitivity*, this type of allergy is characterized by a delayed (hours rather than minutes) reaction to the ingestion of certain foods. This form of allergy generally involves the reaction of certain sensitized cells, usually lymphocytes, to specific chemical substances that trigger the reaction. This type of reaction remains poorly understood at the molecular level. It is known that, ultimately, the reaction destroys cells. Symptoms appear within 6 to 24 hours after ingesting the offending substance.

Symptoms of food allergies are listed in Table 3. Testing for and the treatment of food sensitivities are complex and frequently inadequate. Some of these are described in article on **Dermatitis and Dermatosis**. Treatment frequently requires that the hypersensitive individual alter lifestyles and consistently avoid offending foods. Avoidance diets can be safe and effective, but skilled assistance in outlining such diets should be sought, not only to assure the avoidance of allergens, but also to establish a proper and balanced nutrition program. Accurate diagnosis by a clinical specialist should be sought in contrast with self-diagnosis and parental observations, which frequently may be in error. In addition to information given on labels, most food processors will cooperate with physicians in supplying further detailed food content information when required.

TABLE 3. SYMPTOMS OF FOOD ALLERGIES

Respiratory
Rhinitis — copious watery discharge from mucous membrane of nose
Asthma — pulmonary distress or breathing difficulty
Cutaneous
Urticaria — hives
Eczema/atopic dermatitis — skin rash
Gastrointestinal
Vomiting/nausea
Diarrhea — watery stools, usually with cramping
Other
Angio — edema/edema — swelling, often widespread and severe, especially when affecting the oral/laryngeal area
Anaphylactic shock — severe generalized shock — can result in death
Headache

Source: Institute of Food Technologists' Expert Panel on Food Safety and Nutrition.

Nonallergenic Food Sensitivities. There are several reactions to foods that do not qualify as allergenic because they do not involve the immune system, but that can be serious and annoying. Such reactions include:

(1) **Metabolic food reaction**. An adverse reaction resulting from a defect in metabolism. Such reactions also may be termed "food intolerances." An example is *lactose intolerance* due to a deficiency of the intestinal enzyme lactase, which is essential for metabolism of the milk sugar, lactose. Persons with this intolerance develop nausea, flatus, and diarrhea if milk or some other diary products are ingested.

(2) **Anaphylactoid reaction**. An adverse reaction as the result of eating substances that release, from the body's cellular stores, chemical mediators (triggers) of allergic reactions, such as histamine. There is no immune system involvement associated with food anaphylaxis as previously described. Several foods, including strawberry, shellfish, and chocolate, can induce such reactions.

(3) **Allergy-like food intoxication**. An adverse reaction as the result of ingesting chemical mediators of allergic disease. There are few examples. One includes *histamine poisoning*, also known as *scombroid fish poisoning*. This is most frequently associated with the ingestion of spoiled tuna, mackerel, mahi-mahi, and certain other fishes. (In contrast with prior categories of reactions, this disorder is *not* individualistic. Most people react in a like manner to histamine poisoning.)

(4) **Secondary food sensitivity**. An adverse reaction to a food that occurs with or after the occurrence of another diagnosed condition. Examples include lactose intolerance that is secondary to a gastrointestinal disorder, such as Crohn's disease or ulcerative colitis. Other examples include drug-induced sensitivities, such as the increased sensitivity to tyramine among patients on monoamine oxidase-inhibiting drugs, which

are used as antidepressants; or enhanced sensitivity to histamine among patients who take isoniazid therapy in connection with tuberculosis therapy.

(5) **Food idiosyncrasy**. An adverse reaction that occurs through some unknown mechanism, which even may include psychosomatic illness. Examples include sulfite-induced asthma, Chinese restaurant syndrome, foods associated with migraine headache, among many others. This is a relatively unexplored area, requiring much further research.

Nutritional Equivalency and Bioavailability

Commencing in the 1980s, much attention among nutritionists, food processors and specialists, and government regulators was focused on the concept of *nutritional equivalency*. The basic concept appears simple: What makes two foods or diets of equal value nutritionally? Practical and workable definitions, however, are not so simple, particularly as assessed from the varying viewpoints of scientists, processors, educators, regulators, lawyers, and advocacy groups.

The principle of nutritional equivalency is particularly pertinent when rating and regulating substitute food products. Nearly all authorities agree that current definitions and interpretations of nutritional equivalency require much improvement and clarification.

As of the early 1990s, nutritional equivalency was based on the content of the 20 nutrients for which U.S. recommended daily allowances have been established: protein, vitamins A, C, D, and E, thiamin, riboflavin, niacin, pyridoxine, folacin, cobalamin, biotin, pantothenic acid, calcium, phosphorus, iron, iodine, zinc, and copper. Allowances for numerous other important and essential nutrients remain to be established officially. The absence of a full nutritional profile of a given food remains a major shortcoming of present nutritional equivalency concepts.

Thus, a substitute food can be declared nutritionally equivalent to its traditional counterpart even though it may not contain sufficient amounts of nutrients that are still unlisted. Also, the substitute product may contain excessive amounts of unlisted ingredients, such as sodium. Also, no recognition is given to the ratio of nutrients to energy availability.

With exception of protein efficiency ratios (PER), the legal definition of nutritional equivalency does not consider nutrient *bioavailability*. Admittedly, bioavailability is difficult to determine, to define, and to regulate.

Most contemporary tests of bioavailability concentrate on one ingredient at a time, or, in some cases, several related ingredients-as opposed to the total content of a food. Thus, it is possible that both synergistic and antagonistic effects of various combinations of ingredients may be overlooked. Traditionally, bioavailability testing has fallen into four categories: (1) in vitro analyses, (2) functional tests, (3) determination of excretion patterns of nutrients and their metabolites, and (4) determination of tissue levels of nutrients.

Brain Control Over Diet — Behavioral Reactions to Foods

As with many other sciences, diet and nutritional science is becoming highly interdisciplinary. There is a strong trend for nutrition specialists to become deeply involved in the medical and physiological aspects of diet and for medical professionals to pay much more attention to the importance of diet than in past decades. Exemplary of this trend is the attention given in recent years as to how the diet may affect the brain and, conversely, how the brain influences eating habits, hence health.

A pioneer in the field, R.J. Wurtman (Massachusetts Institute of Technology), working with numerous colleagues, made a number of interesting observations on this topic as early as the 1950s. Prior to that time, medical professionals fully honored the rules of *homeostasis*, which state, in essence, that body chemistry is controlled within relatively narrow limits by a closed-loop system involving a number of feedback loops. The concept of homeostasis was believed to include all of those processes by which the body converts nutrients from the diet into chemicals that it uses to transmit messages, i.e., *neurotransmitters*. Intervening research, however, has shown that homeostasis does *not* govern the production of all neurotransmitters, including some of the most important of these substances, such as acetylcholine, serotonin, norepinephrine, etc. These substances do not appear to be controlled by closed feedback loops, but rather they depend very much on the amount of certain nutrients that "happen" to be available at any given instant. It follows, of course, that this "availability" is strongly influenced by what a person may have ingested at a recent meal or snack. Thus, the close connection between some important neurotransmitters and diet; and thus the close connection between diet and brain and nervous function.

Wurtman et al. suggested an interesting scenario: "The food one digests at a particular time determines the amounts of various nutrients in the blood. These nutrients, in turn, can determine the amount of a particular neurotransmitter produced and released into synapses by the terminals, or endings, of certain nerve cells (neurons). And the amount of the neurotransmitter released each time these neurons fire provides the brain with tell-tale information on the body's nutritional state. This information then helps the brain decide what and when to eat next, and whether to be sleepy or responsive to the environment."

Based essentially on the foregoing premise, Wurtman and other researchers in very recent years have carefully investigated the effects of varying levels of amino acids and hormones and how these affect the direction of the brain over a person's desires involving what and when to eat, of how certain foods affect memory and other brain functions, particularly of the relationship between diet and depression, and how this new knowledge can be useful in treating not only obesity, for example, but very serious brain disorders as well. Thus, many new avenues of research have been initiated.

An excellent review of research findings and an overview of the mechanisms through which diet affects brain function was prepared by Leprohon-Greenwood and Anderson, of which some of the highlights are reported here.

(1) The effect of extremes in nutrient availability, such as that represented by deficiencies sufficient to affect growth rate and brain-cell development in experimental animals, has been well described and dates back well over a decade. This research includes the effects of vitamin and mineral deficiencies in the diet of both humans and other animals

(2) Evidence collected over the past decade demonstrates that brain function responds to several of the characteristics of normal diet, including size and composition of meals and the short-term absence of food. (*Anderson and Johnston*.)

(3) The high metabolic activity of the brain provides evidence that the brain is relatively sensitive to fluctuations in the nutrient state of the other parts of the body. Although the brain constitutes only 2% of adult body weight, it receives 15% of cardiac output and accounts for 20–30% of the body's resting metabolic rate. (*Sokoloff* et al.)

(4) The developed brain has no storable form of energy to meet its high requirements. Hence, it depends upon a continuous supply of oxygen and upon its major energy source, glucose, which crosses the blood-brain barrier by facilitated transport involving the hexose-specific carrier (*Oldendorf*). Because coma appears within 10 seconds of interruption of blood flow, the importance of a constant supply of oxygen and glucose is self-evident.

(5) In contrast with oxygen and glucose, other nutrients are not easily available to the brain because of regulation by the blood-brain barrier. See also **Blood-Brain Barrier**. Lipids may be taken up slowly by diffusion in amounts sufficient to provide essential fatty acids and for normal cell maintenance, but they are insufficient for use as energy sources. The cerebral respiratory quotient of 0.97 indicates that little fat is used to provide energy to the brain under normal conditions. (*Sokoloff* et al.)

(6) Amino acids play key roles in the brain, providing substrate for protein and neurotransmitter synthesis and, to some extent, energy production. In general, free amino acid concentrations in the mature brain approximate those in blood plasma, with exception of glutamine, taurine, glutamate, aspartate, *N*-acetylaspartate, and glycine. The latter are several orders of magnitude higher in concentration. (*Glanville and Anderson*.)

(7) Vitamins A and E are directly involved in neuronal metabolism. The role of vitamin D is indirect, due to its effect on calcium metabolism. Vitamin A is essential to the visual processes of the retina. Vitamin E is believed to function as an antioxidant in the brain, as in other tissues. The water-soluble vitamins function in nerve cells in metabolic reactions similar to those found in other cells. Vitamin B_{12} is involved in transmethylation reactions and in DNA synthesis. Thiamin, riboflavin, niacin, pantothenic acid, pyridoxine, and biotin participate as enzymes in the metabolism of carbohydrates, fats, and amino acids. Vitamin C functions in hydroxylation reactions in the brain, as in other tissues.

(8) Many uncertainties remain regarding the biochemical roles of vitamins and minerals in neurotransmitter metabolism. It is not known whether or not the brain, relative to other tissues, has any special ability

to preserve its metabolic and neurochemical activity during nutrient deficiencies. It is known that folate levels in brain and cerebrospinal fluid are higher than those in the serum even during periods of folate deficiency. Brain neurons use many substances as the chemical links for communication. Such substances known currently include between 30 and 40 amino acids, monoamines, and peptides.

Serotonin, histamine, and cycline use as precursors the dietary essential amino acids, tryptophan, histidine, and threonine, respectively. The catecholamines use tyrosine as precursor. The latter is a dietary semi-essential amino acid available from dietary tyrosine and may also be derived from the essential amino acid, phenylalanine. Acetylcholine requires choline as its precursor. Recent evidence indicates that choline also can be synthesized in the brain from precursors derived from diet and plasma.

(9) The role of vitamins and minerals in brain metabolic processes influencing neurotransmission is still not well defined and merits much further research, particularly in the light of new knowledge of brain neurochemistry. Studies into the relationship between dietary fat and neuronal function is, essentially, just getting underway.

(10) Some researchers have reported that eating protein foods and carbohydrate foods can affect plasma and brain tyrosine concentrations. Protein meals contain tyrosine and increase plasma tyrosine ratio and, therefore, brain tyrosine concentration. In contrast, high-carbohydrate meals, which contain much less tyrosine, tend to decrease plasma tyrosine ratio and hence brain tyrosine concentration. Thus, it would appear that there are at least two possible mechanisms whereby protein foods and carbohydrate foods may have opposite effects upon behavior: (a) variations in serotonin mediated by changes in tryptophan ratio, and (b) changes in cetecholamine turnover mediated by changes in tyrosine ratio. An increase in tryptophan and serotonin following carbohydrate ingestion may perhaps decrease alertness and impair performance (mental). An increase in tyrosine ratio, resulting from protein consumption, could improve mental performance and increase alertness, especially under stressful conditions.

(11) Claims made thus far that high carbohydrate consumption and notably high-sugar diets cause aggressive antisocial behavior have been based mainly on conclusions drawn from anecdotal evidence and, as stressed by some researchers, based upon inadequately designed studies. Claims for beneficial responses from sugar restriction have not been documented using objective experimental procedures. (*Harper and Gans, 1986*.) Research during the early 1990s has cast further doubts on a connection between sugar intake and psychopathic behavior.

(12) Evidence that diet affects behavior of humans and other animals dates back many decades, if not centuries. The hungry carnivore will search out, attack, and kill a quarry that is a potential food source; the well-fed animal will lie quietly and watch the same quarry. It is well established that severe malnutrition in early life will retard brain development. Less severe malnutrition can affect behavioral patterns — attention span, social interactions, and the performance scores on psychological tests of children. But, there are other factors in addition to nutrition present in such situations, including essential isolation of a child from creative, interesting environments, usually because of economic deprivation. How behavioral deficits may be ameliorated through intensive nutritional and sociopsychological therapy and the extent to which such activities may reverse trends remain virtually unknown.

(13) Dietary deficiencies of ascorbic acid, thiamin, niacin, vitamin B_{12}, and iodine can have profound behavioral effects, most of which have been known for decades. Pellagra, a disease associated with niacintryptophan deficiency, can, if untreated, lead to psychosis with delusions and hallucinations. In the 1920s, a test of patients in a mental institution revealed inmates with behavioral changes resulting from pellagra. (*Goodhart and Shils, 1980*.) Accumulation of certain nutrients in the blood and body fluids (in contrast with their absence) also can lead to behavioral changes. These examples occur mainly as the result of genetic defects of amino acid and carbohydrate metabolism. (*Stanbury* et al., *1983*.) When such conditions are not treated shortly after birth, permanent mental deficiency is the frequent result. Phenylketonuria is one of the most intensively studied of such conditions. See also **Phenylketonuria**. Galactosemia, a genetic defect of galactose metabolism, leads to mental retardation, but can be corrected by feeding diagnosed infants with a galactose-free diet. Hypoglycemia and diabetes mellitus, described in separate articles in this encyclopedia, also affect, in varying degrees, moods and mental activity if not controlled.

(14) As early as the 1950s, researchers noted similarities between schizophrenia and the psychosis of pellagra patients. At that time, it was suggested that accumulation of oxidation products of epinephrine was a cause of schizophrenia, and a regimen of nicotinic acid (a methyl-group acceptor) was suggested. Much has been learned since that time. See also **Schizophrenia**.

DIETARY FIBER. Historically, dietary fiber referred to insoluble plant cell wall material, primarily polysaccharides, not digested by the endogenous enzymes of the human digestive tract. This definition has been extended to include other nondigestible polysaccharides, from plants and other sources that are incorporated into processed foods. Cellulose [CAS: 9004-34-6] is fibrous; however, lignin [CAS: 9005-53-2] and many other polysaccharides in food do not have fiberlike structures. See also **Carbohydrates**; **Cellulose**; and **Lignin**.

Cell-wall dietary fiber is a complex system composed of variable amounts of cellulose, other polysaccharides such as hemicellulose [CAS: 9034-32-6] and pectin [CAS: 9000-69-5], and lignin. The precise composition and proportion of polysaccharide types is related to the plant source, stage of maturity, and growing conditions. The composition and physical properties of dietary fiber also may be affected by both postharvest physiological changes and food processing. Cereal grains, legumes, vegetables, and fruits are primary sources of dietary fiber. A smaller proportion of total dietary fiber comes from polysaccharides (gums and mucilages) added for their functionality in processed foods. See also **Hemicellulose**.

The variation in water solubility among polysaccharides results in varied physiological roles. Plant cell-wall polysaccharides and lignin provide insoluble dietary fiber (IDF); nondigestible storage polysaccharides, some pectic polysaccharides, and most of the functional additives contribute soluble dietary fiber (SDF).

A resurgence of interest in dietary fiber has been stimulated by epidemiological evidence of differences in colonic disease patterns between cultures with diets containing large quantities of fiber, and Western cultures having more highly refined diets. Many African countries, for example, are relatively free of diverticular disease, ulcerative colitis, hemorrhoids, polyps, and cancer of the colon. Whereas most interest has focused on the beneficial role of dietary fiber, there is also concern that high fiber diets may cause disturbances in the absorption of nutrients such as minerals and vitamins. The interrelationships between consumption of dietary fiber and health status have been obscured by inadequate knowledge of the quantity and structural chemistry of dietary fiber in various food sources and the physiological roles of the fiber components. See also **Diet**; **Mineral Nutrients**; and **Vitamin**.

Various names have been proposed for the nondigestible part of plant cells, names suggesting either the fibrous nature of some of the cell-wall polysaccharides or their resistance to digestive tract enzymes. Fiber values in food composition tables originally were based on crude fiber analyses, but this assay does not give a true picture of even the fibrous cell-wall material. The term crude fiber is not equivalent to dietary fiber and has little practical meaning. Likewise, the terms unavailable (or nonavailable) carbohydrate and nonnutritive fiber fail to recognize the presence of lignin in fiber or the microbial fermentation of polysaccharides that occurs in the colon. The term nonstarch polysaccharides (NSP) emphasizes the nondigestible character of fiber and is supported by appropriate analytical methodology, but excludes lignin.

Other names have been proposed based on specific methods of analysis. In the Van Soest detergent methods (2), the terms neutral detergent fiber (NDF) or neutral detergent residue (NDR), and acid detergent fiber (ADF) refer to the insoluble hemicellulose–cellulose–lignin complex and to the cellulose–lignin complex of the plant cell wall, respectively. Before the importance of soluble dietary fiber was recognized, NDF was accepted as a measure of dietary fiber even though it reflects insoluble fiber only.

Dietary fiber is the accepted terminology in the United States for nutritional labeling. Total dietary fiber (TDF) and its subfractions, insoluble dietary fiber (IDF) and soluble dietary fiber (SDF), are defined analytically by official methods.

Sources, Composition, and Structure of Dietary Fiber

Natural sources of fiber in the diet include fruits, vegetables, legumes, and cereal grain products. The insoluble fiber content of some processed foods and breads is supplemented by incorporation of purified cellulose, cereal brans, or other plant fiber preparations. Cellulose and its chemically modified derivatives; seaweed polysaccharides, alginates [CAS: 9005-32-7] and carrageenans [CAS: 9000-07-1]; seed mucilaginous polysaccharides, guar and locust bean galactomannans [CAS: 11078-30-1]; highly complex plant exudate polysaccharides, gum arabic [CAS: 9000-01-5], tragacanth [CAS: 9000-65-1], and others; microbially synthesized polysaccharides, xanthan [CAS: 11138-66-2] and gellan gum [CAS: 71010-52-1]; pectins; and other plant polysaccharides are added to foods for a variety of purposes. Because these materials are also nondigestible, they contribute to the total effect of dietary fiber and are encompassed by its definition.

Dietary fiber is a mixture of simple and complex polysaccharides and lignin. In intact plant tissue these components are organized into a complex matrix, which is not completely understood. The physical and chemical interactions that sustain this matrix affect its physicochemical properties and probably its physiological effects. Several of the polysaccharides classified as soluble fiber are soluble only after they have been extracted under fairly rigorous conditions.

Lignin, a highly polymerized alkylaromatic substance, is associated with the decreased digestibility by colonic microbial enzymes of some cell-wall polysaccharides. Lignification also renders the structural polysaccharides less soluble and extractable. The degree of lignification is specific to plant type and increases with plant maturity as the lignin infiltrates the primary and secondary cell walls. Edible plant material has a relatively low content of lignin.

Any starch escaping digestion in the upper gastrointestinal tract also contributes to dietary fiber effects. Some food starches, and the amylose fraction in particular, are readily converted into a nondigestible or slowly digestible physical form under certain food processing conditions. These resistant starches are readily fermented by colonic bacteria. Small amounts of waxes, cutin, and minerals in fruits and vegetables contribute to total dietary fiber values but may be physiologically inert. See also **Starch**.

Physiological Properties

The beneficial effects of dietary fiber, including both soluble and insoluble fiber, are generally recognized. Current recommendations are for daily intakes of 20–35 g in a balanced diet of cereal products, fruits, vegetables, and legumes. However, the specific preventive role of dietary fiber in certain diseases has been difficult to establish, in part because dietary risk factors such as high saturated fat and high protein levels are reduced as fiber levels increase.

Dietary fiber is important in the functioning of the entire gastrointestinal (GI) tract and affects the structure and morphology of the intestine. The process of chewing insoluble fiber-rich foods increases salivation and the flow of gastric secretions. Fiber components that increase viscosity or gel,

for example, guar gum and pectin, delay gastric emptying. Fibers exert buffering action and may alter gastric pH by their effect on gastrointestinal hormones. A reduced glycemic response, probably resulting from delayed absorption of glucose, is associated with various fiber fractions, particularly viscosity-enhancing fibers. See also **Hormones**.

Dietary fiber has a pronounced effect on the characteristics of the fecal mass and on the rate of passage of digest through the GI tract. The particle size and shape, density, and water-holding capacity (WHC) of dietary fiber influence the flow rates. Because hydratability and WHC are determined by chemical structure, crystallinity, overall plant tissue morphology, and lignin content, food processing, such as grinding and heat processing, indirectly affects the rate of passage. Insoluble fiber in the diet increases the rate of passage, frequency of defecation, and the fecal mass, although there are large variations among individuals.

High fiber diets also play a role in the excretion of bile acids and cholesterol [CAS: 57-88-5]. Insoluble fiber, particularly lignin, promotes excretion of bile acids and salts. Viscous soluble fiber components, such as pectin, guar, and soluble $(1 \rightarrow 3)$,$(1 \rightarrow 4)$-β-D-glucan [CAS: 55965-23-6], are associated with a lowering of serum cholesterol and triglycerides in hyperlipemic individuals by an unclear mechanism. There has been concern that high fiber diets might impair absorption of minerals and some vitamins but healthy adults on a balanced diet should not be affected. Epidemiological studies show a negative correlation between colon cancer and high fiber diets; however, a definitive protective role in humans has not been established experimentally. See also **Cholesterol**.

Dietary fiber is degraded extensively in the colon by bacterial action, yielding short-chain fatty acids, primarily acetic acid [CAS: 64-19-7], propionic acid [CAS: 79-09-4], and butyric acid [CAS: 107-92-6], and gases, such as hydrogen, carbon dioxide, and methane. Because the human digestive enzymes known to hydrolyze polysaccharides are amylases, that is, $(1 \rightarrow 4)$-α-D-glucanases [CAS: 9000-90-2], acting in the upper GI tract, dietary fiber was assumed to pass into the colon largely unchanged. However, studies of ileostomy patients have provided evidence that not all of the dietary hemicelluloses are passed from the small intestine into the colon intact, suggesting that some bacterial activity also occurs in the lower small intestine. Colonic bacteria possess inducible enzymes that actively degrade and ferment much of the fiber polysaccharides as well as the mucosal polysaccharides from the host. Some individuals possess bacteria with cellulolytic activity, but hemicelluloses and soluble polysaccharides are more actively fermented.

Fiber components are the principal energy source for colonic bacteria with a further contribution from digestive tract mucosal polysaccharides. Rate of fermentation varies with the chemical nature of the fiber components. Short-chain fatty acids generated by bacterial action are partially absorbed through the colon wall and provide a supplementary energy source to the host. Therefore, dietary fiber is partially caloric. The short-chain fatty acids also promote reabsorption of sodium and water from the colon and stimulate colonic blood flow and pancreatic secretions. Butyrate has added health benefits. Butyric acid is the preferred energy source for the colonocytes and has been shown to promote normal colonic epithelial cell differentiation. Butyric acid may inhibit colonic polyps and tumors. The relationships of intestinal microflora to health and disease have been reviewed.

Physicochemical Properties

Several physicochemical properties of dietary fiber contribute to its physiological role. Water-holding capacity, ion-exchange capacity, solution viscosity, density, and molecular interactions are characteristics determined by the chemical structure of the component polysaccharides, their crystallinity, and surface area.

Dietary fiber and fiber-rich food fractions bind bile acids and bile salts in vitro. This interaction is more pronounced for the lignin component.

Analysis of Dietary Fiber

Analytical methods suitable for routine assays measure groups of fiber components having similar solubility properties. Values may be expressed as *total dietary fiber (TDF)*, *insoluble dietary fiber (IDF)*, or *soluble dietary fiber (SDF)*. The more commonly used fiber analysis methods are detergent methods for cell-wall fiber, enzymatic gravimetric methods for soluble and insoluble polysaccharides, and methods that include a quantitative analysis of the component sugars in the fiber fractions. The method selected defines IDF and SDF, since solubility of polysaccharides is affected by temperature and pH.

Sources of Dietary Fiber for Processed Foods

An increasing number of fiber sources are available for food processing, representing a diversity of sources and technological advances. Commercial food-grade purified cellulose products and cereal brans are used in food products to enhance the fiber content or for other functional purposes. Many purified or partially purified nondigestible polysaccharides are used in food systems for their physicochemical properties, for example, for viscosity or as suspending agents. These polysaccharides contribute to the dietary fiber content even though they are not used for that purpose.

High quality purified cellulose is prepared from soft or hard woods by pulping methods that remove most of the associated hemicelluloses, lignin, waxes, and other constituents. The pulp is then bleached to give a white cellulose (-cellulose) that is a relatively pure (>90%) $(1 \rightarrow 4)$-β-D-glucan. Although the main intent is to degrade and remove the lignin and hemicelluloses, the cellulose, too, may be partially depolymerized. Purified fibrous cellulose is white, odorless, and nonabrasive. Although devoid of flavor, it possesses an undesirable texture in the mouth related to its fibrous nature, particle size, and insolubility. Other cellulosic products are made from the cellulose pulp or -cellulose.

Solka-Floc, a purified fibrous powdered cellulose, is said to be 99% cellulose on a dry weight basis, virtually lignin free, free of fat and protein, and with low ash content. Food grades are available in fiber lengths averaging 20–25 to 100–140 μm.

Limited hydrolysis of fibrous cellulose pulp yields a product more highly crystalline than native cellulose. Mineral acids hydrolyze glycosidic bonds in the less crystalline regions of the cellulose fibers. The resulting cellulose microcrystals can be mechanically dispersed in water to give a gel or emulsionlike colloidal suspension for use in low calorie whipped toppings as well as in low fat or fat-free emulsions that mimic oil-in-water emulsions at cellulose concentrations in the 0.75–3% range. These microcrystals, like the native cellulose, do not melt and can be used in food systems under heat-processing conditions that would destroy the emulsion stability of fat- and oil-based systems.

Microcrystalline celluloses are marketed under the trade name Avicel. The physical characteristics of microcrystalline celluloses differ markedly from those of the original cellulose. The free-flowing powders have particle sizes as small as 0.2–10 μm. Avicel celluloses coated with xanthan gum, guar gum, or carboxy-methylcellulose to modify and stabilize their properties are also available. The Avicel products are promoted for use in low calorie whipped toppings and icings and in fat-reduced salad dressings and frozen desserts.

Chemical modification markedly alters the physical properties of cellulose. Common derivatives include methylcellulose [CAS: 9004-67-5], ethylcellulose [CAS: 9004-57-3], propylcellulose [CAS: 9005-18-9], hydroxyethylcellulose [CAS: 9004-62-0], hydroxypropylcellulose [CAS: 9004-64-2], and carboxymethylcellulose (CMC) [CAS: 9000-11-7] as well as mixed ethers of cellulose. These derivatives are obtained by alkylation of the cellulose under basic conditions. The ether substituents disrupt the extensive hydrogen bonding in the cellulose and permit increased hydration. At certain degrees of substitution the insoluble cellulose is transformed into a water-soluble colloid. The nature and size of the substituent, the regularity of substitution, and the molecular weight of the cellulose determine the degree of substitution at which water solubility occurs. In addition to increased hydration, CMC displays increased ion-exchange capacity. These cellulose ethers are used in food products for enhanced water retention, reduction of oil absorption in fried foods, and as thickeners and binders. See also **Food Additives**. Consumer products include Methocel methylcellulose, Benecel methyl-cellulose, hydroxypropylcellulose, and Ticalose CMC.

Development of a new strain of Acetobacter may lead to economical production of another novel cellulose. Cellulon fiber has a very fine fiber diameter and therefore a much larger surface area, which makes it physically distinct from wood cellulose. Its physical properties more closely resemble those of the microcrystalline celluloses; thus it feels smooth in the mouth, has a high water-binding capacity, and provides viscous aqueous dispersions at low concentration. It interacts synergistically with xanthan and CMC for enhanced viscosity and stability.

Bran fractions are more concentrated sources of fiber than are grain flours. As a fiber supplement in foods, cereal grain brans are more representative of natural dietary fiber than is cellulose because bran contains hemicelluloses, lignin, and cellulose. The composition and properties of bran are dependent on the cereal grain source, plant variety, and milling practices. Varying amounts of the endosperm components are present, and the particle size depends on the break roll from which the bran is taken. Wheat bran contains a large proportion of arabinoxylans, considerable lignin, and some starch in addition to cellulose. Wheat brans are readily available from any flour mill. Brans from corn, oats, barley, and rice are also available and differ from wheat bran in composition and properties. Oat bran and barley bran, for example, contain high proportions of (1 $\rightarrow$ 3), (1 $\rightarrow$ 4)-β-D-glucans, part of which is soluble fiber, and little or no pectin. Oatrim products, developed at the National Center for Agricultural Research (ARS), Peoria, Illinois, contain up to 10% of the β-glucan. Rice brans are available in grades ranging from defatted bran (0.5–1.5% oil, 30–40% TDF) to stabilized full fat (18–22% oil, 25–30% TDF). Oat, barley, and rice brans contain significant amounts of soluble fiber, in contrast with wheat bran.

The American Association of Cereal Chemists (http://www.aaccnet.org/) has made available a certified food grade wheat bran as a reference standard for research purposes. This bran is a blend of soft white wheat (87.3%) and club white wheat (12.7%).

Polysaccharides of diverse and frequently complex structure and origin are used as food additives for their functional properties, viscosity, emulsification, bodying and suspending, water binding, gelation, and fat-mimicking texture. They are used at relatively low levels (up to about 3%) and are regulated by the FDA for specific functional purposes. These polysaccharides tend to be water-soluble and contribute to SDF. They are usually classified by source, that is, seaweed or algal, microbial, plant exudate, legume seeds, and tubers.

DIFFERENCE. The result obtained by subtraction of numbers or other quantities. Also called the remainder.

An especially useful and important type is a finite difference. Its properties are studied in the calculus of finite differences, sometimes called the twin sister of differential and integral calculus. It is applied to problems of interpolation, approximate differentiation and integration, summation of series, and to solutions of difference equations, the analogue of differential equations.

Let $y_0, y_1, y_2, \ldots$ be values of $y = f(x)$ let the corresponding values of the independent variable be $x_0, x_1, x_2, \ldots$ and define a first divided difference as

$$[x_i x_j] = (y_i - y_j)/(x_i - x_j)$$

Second, third, etc., divided differences eventually lead to the nth difference

$$[x_0 x_1 \ldots x_n] = \frac{[x_0 x_1 \ldots x_{n-1}] - [x_1 x_2 \ldots x_n]}{x_0 - x_n}$$

After some manipulation, one obtains

$$y = f(x) = f(x_0) + (x - x_0)[x_0 x_1] + (x - x_0)(x - x_1)[x_0 x_1 x_2] + \cdots + (x - x_0)\ldots(x - x_{n-1})[x_0 x_1 \ldots x_n] + R(x)$$

where $R(x)$ is the remainder. This formula makes it possible to calculate $y = f(x)$ at some value intermediate between tabulated numbers $x_0, x_1, x_2, \ldots$ and $y_0, y_1, y_2, \ldots$ but the procedure is less laborious if the x_k are evenly spaced, so that $x_n - x_0 = nh$, where n is an integer. These quantities could be, for example, numbers taken from a table of logarithms or trigonometric functions. They might also be the result of some experimental measurement. In the latter case, if the measurements were not made at equally spaced values of x, graphical interpolation could be used to get such numbers.

First differences are then defined as

$$\Delta y_0 = y_1 - y_0; \Delta y_1 = y_2 - y_1; \ldots; \Delta y_{n-1} = y_n - y_{n-1}$$

Second differences, third differences, etc., are defined in a similar way and the $(n + 1)$th order differences are

$$\Delta^{n+1} y_0 = \Delta^n y_1 - \Delta^n y_0; \Delta^{n+1} y_1 = \Delta^n y_2 - \Delta^n y_1, \ldots$$

By successive substitution, it is found that

$$\Delta^n y_k = \sum_{r=0}^{n} (-1)^r \binom{n}{k} y_{k+n-r}$$

Quantities of this kind are called diagonal or forward differences.

If $\Delta^m y_k$ is such a diagonal difference of mth order, a horizontal difference is defined as

$$\Delta_m y_{k+m} = \Delta^m y_k \quad \text{or} \quad \Delta_m y_n = \Delta^m y_{n-m}$$

Differences of either kind are conveniently displayed in a difference table, which is shown for the case where horizontal differences are used. Other types can be constructed in a similar way:

x	y	$\Delta_1 y$	$\Delta_2 y$	$\Delta_3 y$
x_0	y_0			
x_1	y_1	$\Delta_1 y_1$		
x_2	y_2	$\Delta_1 y_2$	$\Delta_2 y_2$	
x_3	y_3	$\Delta_1 y_3$	$\Delta_2 y_3$	$\Delta_3 y_3$

If h is the interval between equally spaced values of the argument in such a table, constructed from $y = f(x)$, it is often convenient to define

$$\delta f(x) = f(x + h/2) - f(x - h/2)$$

$$\mu f(x) = \tfrac{1}{2}\delta f(x)$$

A central difference, formed by the first of these operators, is related to a finite difference by the equation

$$\delta^m y_{n/2} = \Delta^m y_{(n-m)/2}$$

where m and n are integers, both even or both odd.

For some uses of differences of these types, see **Interpolation**.

DIFFERENCE EQUATION. Instead of variables and derivatives, $x, y, y', y'', \ldots$, as in differential equations, a difference equation contains variables and finite differences, $\Delta y, \Delta^2 y$, etc. It is convenient to change the independent variable from x to s, where $x = hs$, $\Delta x = h$ and then $\Delta s = 1$. With u as the dependent variable, $\Delta u_s = u_{s+1} - u_s$, $\Delta^2 u_s = u_{s+2} - 2u_{s+1} + u_s$, hence the equation may be written in terms of s, u_s, u_{s+1}, etc.

A linear difference equation, the simplest type studied, is

$$\sum_{i=0}^{n} f_i(s) u_i(s) = \phi(s)$$

which is inhomogeneous; homogeneous, if $\phi(s) = 0$. Difference and differential equations are similar in many properties but their solutions are quite unlike. Given an initial value, u_0, one could proceed step-by-step for a first-order case and calculate a table of particular solutions for integral values of s. This could be called a particular discrete solution for it will be a special case of a particular continuous solution containing an arbitrary constant, determined to satisfy the initial conditions. However, this is not the general solution.

Consider $f(s, u_s, w) = 0$ where w is any periodic function with period of unity. Then $f(s + 1, u_{s+1}, w) = 0$ and, by elimination, one obtains $F(s, u_s, u_{s+1}) = 0$, the given difference equation of order one. The solution containing such a periodic function is then the general solution.

By analogy with the case of integral calculus, one may find inverse equations to difference equations. Thus, as simple examples: for product, $\Delta u_s v_s = v_{s+1}\Delta u_s + u_s \Delta v_s$; for a power, $\Delta s^{(n)} = n s^{(n-1)}$, etc. With a suitable collection of such formulas, the work of solving a difference equation proceeds in a manner similar to that for a differential equation.

DIFFERENCE OF LATITUDE. The shorter arc of any meridian between the parallels of two places, expressed in angular measure.

DIFFERENCE OF LONGITUDE. The smaller angle at the pole or the shorter arc of a parallel between the meridians of two places, expressed in angular measure.

DIFFERENTIAL ANALYZER. An analog computer designed and used primarily for solving differential equations.

DIFFERENTIAL CORRECTION. In celestial mechanics, a method for finding from the observed residuals minus the computed residuals (O−C) small corrections which, when applied to the orbital elements or constants, will reduce the deviations from the observed motion to a minimum.

DIFFERENTIAL EQUATIONS. In mathematical terms a differential equation is an equation that involves a function or a set of functions and its derivatives. If the function or set of functions is a function of only one variable the differential equation is called an ordinary differential equation or ODE. If the function or set of functions is a function of more than one variable the differential equation is called a partial differential equation or PDE. The solution to the ODE or PDE is the function or set of functions that makes the differential equation true.

In mathematical notation an ODE has the form

$$F(t, y'(t), \ldots, y^{(n)}(t)) = 0,$$

where $y'(t)$ is the first derivative of y with respect to the variable t, $y^{(n)}(t)$ is the nth derivative of y with respect to t. The solution is the function y of the variable t that makes the equation true. The natural number n is called the degree or order of the ODE.

For example

$$y'(t) = y' = 2y(t) = 2y$$

is a first-order ODE in the function y. A solution to this ODE is

$$y = ce^{2t},$$

where c is an arbitrary real number (constant), since

$$y' = 2ce^{2t} = 2y.$$

To determine the constant c an *initial value* or *initial condition* for y is usually given. For example, if $y(0) = 3$ is the initial condition then

$$y(0) = ce^0 = c = 3$$

and

$$y = 3e^{2t}$$

is the solution satisfying the initial condition. The ODE

$$u'' + u = \cos t$$

is a second-order ODE in $u = u(t)$. A solution to this ODE is

$$u = c_1 \cos t + c_2 \sin t + \tfrac{1}{2} t \sin t.$$

The ODE's

$$y_1' = 2y_1 - 4y_2 + \cos t$$
$$y_2' = -y_1 + 2y_2 + 3$$

are called a first-order system of two ODEs in the two unknowns y_1 and y_2. A solution to this system of ODE's is

$$y_1 = c_{1,1}e^{4t} + c_{1,2} + \frac{9}{17}\sin t - \frac{2}{17}\cos t$$
$$y_2 = c_{2,1}e^{4t} + c_{2,2} + \frac{4}{17}\sin t + \frac{1}{17}\cos t$$

The system of ODEs

$$y_1'' = 2y_1' - 3y_3 + 2t$$
$$y_2'' = 2y_1 + \cos(y_2) - 4\sin t$$
$$y_3'' = 3y_1 - 2ty_3'$$

is a second-order system of three ODE's in the three unknowns y_1, y_2 and y_3.

In mathematical notation a PDE has the form

$$F\left(x_1, \ldots, x_m, y(x_1, \ldots, x_m), \frac{\partial}{\partial x_1} y, \ldots, \frac{\partial}{\partial x_m} y, \ldots, \frac{\partial^n}{\partial x_1^{n_1} \ldots \partial x_m^{n_m}} y\right) = 0$$

and a system of k PDE's has the form

$$F_1\left(x_1, \ldots, x_m, y_1(x_1, \ldots, x_m), \ldots, y_k(x_1, \ldots, x_m), \frac{\partial}{\partial x_1} y_1, \ldots, \frac{\partial}{\partial x_m} y_1, \ldots, \frac{\partial^n}{\partial x_1^{n_1} \ldots \partial x_m^{n_m}} y_k\right) = 0$$

$$F_2\left(x_1, \ldots, x_m, y_1(x_1, \ldots, x_m), \ldots, y_k(x_1, \ldots, x_m), \frac{\partial}{\partial x_1} y_1, \ldots, \frac{\partial}{\partial x_m} y_1, \ldots, \frac{\partial^n}{\partial x_1^{n_1} \ldots \partial x_m^{n_m}} y_k\right) = 0$$

$$F_k\left(x_1, \ldots, x_m, y_1(x_1, \ldots, x_m), \ldots, y_k(x_1, \ldots, x_m), \frac{\partial}{\partial x_1} y_1, \ldots, \frac{\partial}{\partial x_m} y_1 \ldots, \frac{\partial^n}{\partial x_1^{n_1} \ldots \partial x_m^{n_m}} y_k\right) = 0.$$

That is, a PDE involves a function y or a system of functions $y_1, \ldots, y_k$ that depend on the variables $x_1, \ldots, x_m$. A solution is a function or system of functions that make the equation true.

For example, the first-order PDE

$$\frac{\partial u}{\partial t} = u_t = \frac{\partial}{\partial x} u = u_x$$

has the solution

$$u(x, t) = f(x + t)$$

for an arbitrary function f. If the initial condition

$$u(x, 0) = \sin x$$

is given, then

$$u(x, 0) = f(x) = \sin x$$

and the solution satisfying the initial condition is

$$u(x, t) = \sin(x + t).$$

The first-order system of PDE's

$$u_t = w_x$$
$$w_t = u_x$$

has the solution

$$u(x, t) = f(x + t) + g(x - t)$$
$$w(x, t) = f(x + t) - g(x - t)$$

Some of the technical issues associated with ODE's and PDE's are

1. Does a solution exist?
2. Is there more than one solution?
3. What are the proper initial conditions?
4. What is the behavior of the solutions?
5. If a solution exists how do we find it?

For many ODEs and PDEs the solution can be shown to exist and be the only solution, yet the solution cannot be found. In these cases numerical methods are developed that approximate the solution. These numerical methods are run on computers. The numerical values obtained from the computers are plotted in some meaningful fashion. These plots are analyzed to determine properties of the solutions. Some questions arising from the numerical methods are:

1. How close does the numerical values approximate the true values?
2. Does the numerical method converge to the exact solution?
3. How stable is the numerical method?
4. What properties of the numerical solution arise from the differential equation and what properties arise from the numerical method?

Many ODE's and PDE's arise from studying things that change. For example, the English physicist and mathematician Isaac Newton discovered the laws of physics that describe how objects move, for example, planets,

fluids, and balls. Populations increase or decrease over time, interest rates decrease or increase over time and the price of stock options decrease over time. For example, the logistic ODE

$$N' = \alpha N - \beta N^2; N(0) = P$$

is used by biologists to model the population of a single species. The ODE

$$\theta'' + G \sin\theta = 0; \theta(0) = \alpha, \theta'(0) = \beta$$

describes the (frictionless) motion of a pendulum bob. This equation is derived from Newton's laws. The function θ is the angle the pendulum bob makes with the vertical. The PDE

$$p_t = -\sigma^2 S^2 p_{ss} + \alpha S p_s - rp; p(s, 0) = F(s)$$

is used to model the price of a stock option where S is the price of the option and t is time. These equations were developed by Fischer Black, Robert Merton, and Myron Scholes. They received the Nobel prize in economics for their discovery. The system of PDE's

$$\rho_t + (\rho v)_x = 0$$
$$(\rho v)_t + (\rho v^2 + c^2 \rho)_x = 0$$

is used to describe the density, ρ and velocity v of a moving fluid. These equations were derived by the Swiss mathematician Leonard Euler from Newton's laws.

DIFFERENTIAL GEOMETRY. See **Geometry**.

DIFFERENTIAL LEVELING. Differential leveling is a system of surveying whereby the difference in elevation of two remote points is obtained through the use of the surveyor's level and level rod. A chain or tape is not needed. The procedure in differential leveling is illustrated in Fig. 1. BM_1 represents a known benchmark. The elevation of BM_2 is to be found. The rod is held on BM_1 and the level set up so as to take a back sight on the rod. The rodman then advances to a turning point chosen by the instrument operator, and the telescope is swung around for a foresight reading on the rod. The levelman then advances the instrument to a new position, from which he takes a back sight on the rod, which is still at the turning point. This procedure is continued until the rodman reaches the sight of BM_2. The back sight reading, added to the elevation of BM_1, gives the elevation of the level at the first station. The foresight reading, subtracted from the instrument elevation, gives the elevation of the turning point. In this way, by additions and subtractions of back sight and foresight readings, the total difference of elevation between BM_1 and BM_2 is determined. See also **Level (Surveyor's)**.

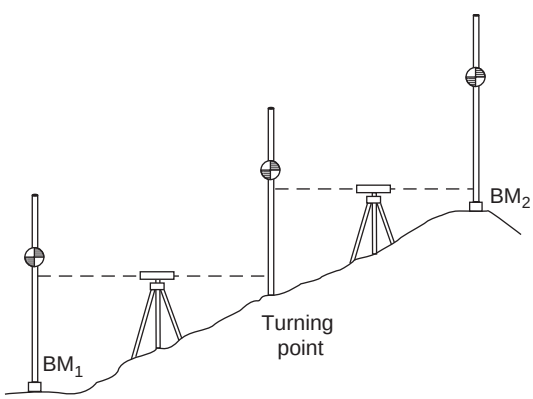

Fig. 1. Differential leveling.

The field work necessary for determining the elevation of points along a given line such as the center line of a railroad, airport runway, or highway is called profile leveling. Rod readings are taken at regular intervals and also at points of abrupt change of slope. The outline of a vertical section through the center line is called a profile. The profile is obtained by plotting elevations that are the result of profile leveling. Lasers are now used by surveyors in leveling operations, notably in the grading of land for irrigation. See also **Irrigation**.

DIFFERENTIAL MANOMETER. A device for measuring small pressures. The device is best explained by referring to Fig. 1. A U-tube, equipped with an enlarged section (c) at the top of each side, has in it two immiscible liquids, a lower (heavier) liquid F and an upper (lighter) liquid E. If a pressure difference be set up across A and B, the liquid F will change position, giving a head D to compensate for the pressure. Because of the enlargements in the upper tubes the top level of liquid E changes a negligible amount. The head equivalent to the pressure varies inversely as the difference between the densities of liquids E and F. By selecting the proper liquids, the difference can be made very small, making for a large head. Thus a pressure which would give only a small reading on an ordinary manometer can be made to produce a large reading on a differential manometer, thus increasing the accuracy of measurement.

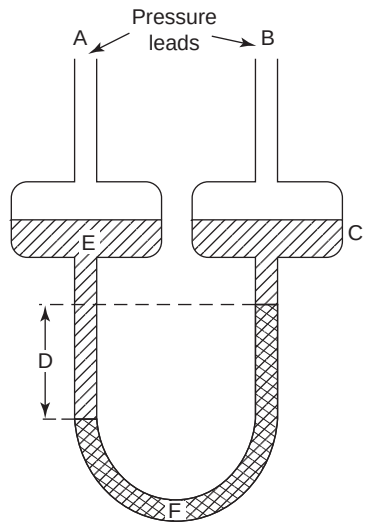

Fig. 1. Cross section of a differential manometer.

Differential manometers are widely used in industrial instruments, not only for pressure measurements per se, but in flowmeters, liquid-level meters, and specific gravity meters — where a pressure difference is indicative of a change in another variable. A widely used configuration is in an orifice type flowmeter. Detection of manometer level changes can be accomplished automatically by way of floats, induction coils, and other sensors.

DIFFERENTIAL (Mathematics). If the variable y depends on the single independent variable x, so that $y = f(x)$, their differentials are designated by dy and dx. If $dx \neq 0$, the ratio of the differentials is the derivative of y with respect to x

$$dy/dx = f'(x)$$

Given a function of several independent variables, the total or complete differential is a sum of terms containing partial derivatives as coefficients

$$d\phi(x, y, z, \ldots) = \frac{\partial \phi}{\partial x} dx + \frac{\partial \phi}{\partial y} dy + \frac{\partial \phi}{\partial z} dz + \cdots$$

To emphasize the fact that the function of $d\phi$ has been obtained by differentiation, it is also called an exact or perfect differential.

DIFFERENTIAL-MODE VOLTAGE. The voltage which appears between two terminals or other points in a circuit, neither of which is necessarily at the system reference potential (usually designated as ground) is

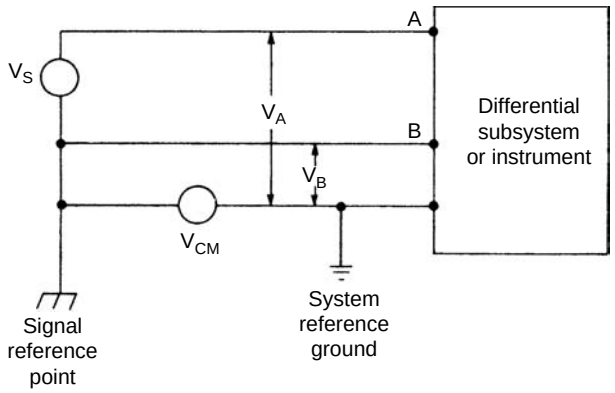

Fig. 1. Differential-mode voltage.

termed the differential- (or normal)- mode voltage. In Fig. 1, $V_A - V_B$ is the differential input voltage. A perfect differential system would indicate only the value of the differential signal voltage V_S. However, in practical installations, unbalances and inaccuracies in the system often result in conversion of some of the common-mode voltage into a differential-mode signal. These causes are described in some detail under **Common-Mode Voltage**.

THOMAS J. HARRISON,
IBM Corporation, Boca Raton, FL

DIFFERENTIAL TOPOLOGY. See **Topology**.

DIFFERENTIAL (Vehicle). As a 4-wheel vehicle rounds a corner, the outer wheels travel a greater distance than the inner. The wheels on a wagon are mounted on a dead axle, so that they turn independently of each other. On a live axle, some device that will permit them to revolve at different speeds to compensate for the difference in travel when rounding a curve is necessary. The fundamental operating principle of a simple bevel gear differential is illustrated in Fig. 1. The driveshaft A has mounted on it pinion B, which drives gear C. If it were not for the necessity of rounding curves, gear C could be rigidly fixed to the live axle KK. The differential action is obtained as follows: Gear C is not keyed to the axle. The spider E is rigidly fastened to the gear and has mounted on it, free to turn, the bevel gear G. Gear G meshes with gears H_1 and H, each of which is keyed to a half of the axle. When traveling straight ahead, gears G, H_1, and H revolve with the spider, but do not have any motion relative to each other. When rounding a curve, one wheel must travel faster than the other. The difference in rotation of the axle is compensated for by rotation of the differential gear G on its pin F. Any accelerated motion of one wheel is offset by a retarded motion of the other.

See also **Automotive Engineering**.

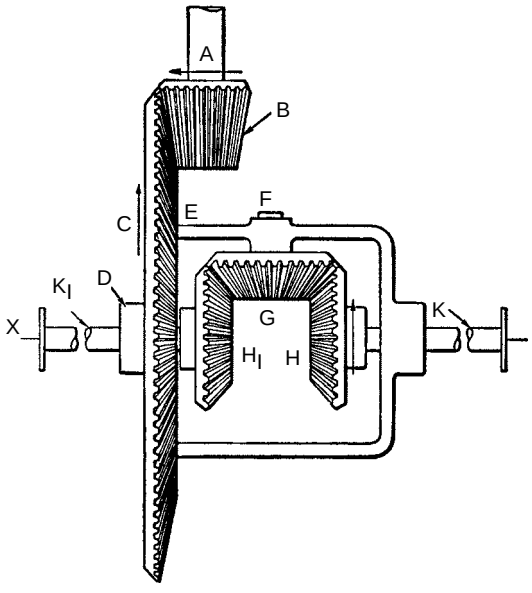

Fig. 1. Schematic representation of a classical bevel gear differential for illustration of fundamental operating principle. There are numerous other differential designs.

DIFFERENTIATION (Geology). The general process of formation of different types of igneous rocks from a common parent magma. In a broader sense, the term signifies crystallization or recrystallization phenomena that occur in magma as it cools.

DIFFERENTIATION (Mathematics). Differentiation is the process of finding the derivative of a function with respect to the independent variable. The methods of calculus are used to determine the derivative for certain elementary functions and two or more of the resulting rules are combined to obtain derivatives for more complicated functions. In the following table y, u, v, w are functions of the independent variable x; A, B, C are constants; $y' = dy/dx$; $u' = du/dx$, etc. See also **Derivative (Mathematics)**.

Algebraic Functions

1. $y = u \pm v \pm w \pm \cdots$; $y' = u' \pm v' \pm w' \pm \cdots$; $y = C$; $y' = 0$.
2. $y = Au \pm Bv \pm Cw \pm \cdots$; $y' = Au' \pm Bv' \pm Cw' \pm \cdots$.
3. $y = uv$; $y' = uv' + u'v$; $y = uvw \cdots$; $y' = vwu' + uwv' + uvw' + \cdots$; $y = uv$; $y'/y = u'/u + v'/v$.
4. $y = u/v$; $y' = (vu' - uv')/v^2$; $y = A/v$; $y' = -Av'/v^2$.
5. $y = u^n$; $y' = nu^n - {}^1u'$, where n is any positive or negative integer or fraction, rational or irrational number but independent of x.
6. If u is a function of x and $\phi(u)$ is a function of u, $\phi' = d\phi/dx = (d\phi/du)(du/dx)$.
7. If $x = \phi(y)$ is the inverse function to $y = f(x)$, $d\phi/dy = 1/f'(x)$.

Transcendental Functions

8. $y = e^u$; $y' = e^u u'$; $y = a^u$; $y' = a^u \ln a u'$, where a is independent of x.
9. $y = \ln u$; $y' = u'/u$; $y = \log_a u$; $y' = \dfrac{u'}{u \ln a}$.
10. $y = \sin u$; $y' = \cos u u'$.
11. $y = \cos u$; $y' = -\sin u u'$.
12. $y = \tan u$; $y' = \sec^2 u u'$.
13. $y = \cot u$; $y' = -\csc^2 u u'$.
14. $y = \sec u$; $y' = \sec u \tan u u'$.
15. $y = \csc u$; $y' = -\csc u \cot u u'$.
16. $y = \sin^{-1} u$; $y' = u'/\sqrt{1 - u^2}$.
17. $y = \cos^{-1} u$; $y' = -u'/\sqrt{1 - u^2}$.
18. $y = \tan^{-1} u$; $y' = u'/(1 + u^2)$.
19. $y = \cot^{-1} u$; $y' = -u'/(1 + u^2)$.

For higher-order derivatives, the Leibniz rule is often useful. Partial derivatives are found by methods similar to those described here for ordinary derivatives.

DIFFERENTIATION (Numerical). A method for calculating the numerical value of the derivative of a function at a given point (x_0, y_0). Graphical or mechanical processes may be used, but more commonly the function is approximated by an interpolation formula which is then differentiated by the rules of calculus. Since the constant term in the interpolation polynomial is lost on differentiation, the series converges more slowly than the original formula. One cannot then hope for highly accurate results in numerical differentiation. Often a carefully made plot on a large scale is more satisfactory than any other method of finding a numerical derivative, for the slope of such a plot can be determined with some precision.

DIFFERENTIATION UNDER THE INTEGRAL SIGN. For the differentiation of a definite integral of a function $f(x, m)$ containing a parameter m, when the limits of the integral are constants a and b,

$$\frac{d}{dm}\int_a^b f(x,m)dx = \int_a^b \frac{\partial f}{\partial m}dx$$

and when the limits of the integral are u and v, functions of m,

$$\frac{d}{dm}\int_u^v f(x,m)dx = \int_u^v \frac{\partial f}{\partial m}dx + f(v,m)\frac{dv}{dm} - f(u,m)\frac{du}{dm}$$

DIFFRACTION. In any wave disturbance, the interference pattern resulting from the rays passing through different parts of an opening, or coming from different points around an opaque object, as they unite at each point. Diffraction and interference effects are characteristic of all wave phenomena no matter of what type. They are thus found in electromagnetic waves (light, x-rays, etc.), sound waves, water waves, and in matter waves. Diffraction occurs whenever a wave passes through a restricted aperture, such as a small hole or slit, or around an edge or particle. An example in optics is the case in which light from a point source passes the edge of a postcard and falls upon a white screen; the shadow of the edge is not sharply defined, but deepens to darkness gradually on one side, and is bordered by very narrow alternate bright and dark interference fringes (*diffraction bands*) on the other. (See also **Wave Propagation (Huygen's Principle)**.) Again, the image of a minute opaque speck under magnification against a bright background is surrounded by concentric diffraction rings. The image of a bright object, such as a star, as formed in the focal plane of a converging lens, is also surrounded by diffraction rings. If two such images are close together the fringe systems will overlap and no matter how much magnification is applied it will never be possible to obtain clear, well-separated, images of the points. The resolving power of an optical instrument may be defined as a measure of the sharpness with which small images very close together may be distinguished. It is directly proportional to the diameter of the objective aperture and inversely proportional to the wavelength of the light. Diffraction thus limits the resolving power, and hence the practicable magnification, of optical instruments.

Diffraction always results in energy being carried into regions that it could not reach if the propagation of the wave were strictly rectilinear. The patterns produced are geometrically similar whenever the ratio of the wavelength to the dimensions of the aperture is the same. Thus a radio wave in the AM broadcast range will be diffracted in passing through a hole 15 meters in diameter to the same extent as blue light passing through a pin-hole of 0.001 millimeter diameter.

For a single slit of width a and light of wavelength λ, falling on the slit at normal incidence, the intensity of light at an angle θ from the normal to the slit is given by

$$I = R_0^2 \frac{\sin^2\left(\frac{\pi a \sin\theta}{\lambda}\right)}{\left(\frac{\pi a \sin\theta}{\lambda}\right)^2}$$

Fresnel diffraction. The intensity at any point is the resultant of disturbances coming directly to that point from all parts of the exposed wave front. In general, the wave front is spherical or cylindrical, resulting from a source at finite distance, and the point of observation is also at finite distance.

Fraunhofer diffraction phenomena are observed when both the source and the point of observation are effectively at infinite distance from the diffracting object, obstacle, or aperture. This condition is sometimes brought about by passing the light from the source through a collimator before it is diffracted, and then focusing the parallel diffracted rays at the point of observation.

For material particles, according to the de Broglie hypothesis and quantum mechanics, a material particle having a momentum of magnitude p behaves as though it were associated with a wave of wavelength $\lambda = h/p$, where h is the Planck constant. In any physical process in which a particle interacts simultaneously with two or more scattering centers, the waves associated with the scattering from the various centers will undergo interference with one another to produce diffraction analogous to that which would be observed with light of the same wavelength. According to the principles of quantum mechanics, the wave which is associated with the particle is described by the quantum mechanical wave function $\psi(r, t)$ which contains all of the information concerning the state of the particle which one is physically allowed to have. Born showed that $\psi^*(r, t)\psi(r, t)d\tau$ should be interpreted as the probability that the particle will be found in the volume element dt. Thus in regions where the wave functions representing the scattering from the different scattering centers give complete destructive interference, the probability of finding the particle will be zero. In regions where constructive interference occurs, the probability of finding the particle will be enhanced.

The analogy between the diffraction of light, x-rays, etc., on one hand and that of material articles on the other becomes clear if we remember that in the former phenomena it is the probability of finding a photon in a given location that is determined by the square of the absolute value of the wave amplitude. Because it is relatively easy to use electrons or neutrons having wavelengths of the order of one angstrom, electron and neutron diffraction may be used to study crystal structure in a manner very similar to x-ray diffraction. Electrons do not penetrate as deeply into matter as do x-rays, hence electron diffraction reveals structure near the surface; neutrons do penetrate easily and have the advantage that they possess an intrinsic magnetic moment that causes them to interact differently with atoms having different alignments of their magnetic moments.

DIFFRACTION GRATING. A series of very fine, closely spaced parallel slits, or of very narrow, parallel reflecting surfaces, which, when light is incident upon it at a definite angle, produces a succession of spectra. The complete optical theory is somewhat complicated, but the action of a plane transmission grating may be explained approximately as follows.

A plane, monochromatic light wave W, incident at angle i Fig. 1, reaches the slits at different times. A lens L receives the waves emerging from any two adjacent slits, A and B (among many others), after they have traveled paths differing by $CA + AD$; that is, by $S \sin i + S \sin \delta$, in which $S = AB$. If the lens is so placed that this path difference is a whole number of wavelengths, $n\lambda$, the successive wave-trains will reach it in the same phase, so that when they are brought to the focus F, they will be in synchronism and will produce a bright image of the distant source. Therefore any angle δ for which this result is possible is subject to the condition

$$S \sin i + S \sin \delta = n\lambda$$

or

$$\sin \delta = \frac{n\lambda}{S} - \sin i$$

Bright images will be produced for those angles δ which correspond to $n = 1, 2, 3, 4, \ldots$; the numbers denote the "orders" of the images. It is easily shown that for any order the total deviation $(i + \delta)$ is least when $\delta = i$ and therefore when

$$\sin \delta = \frac{n\lambda}{2S}$$

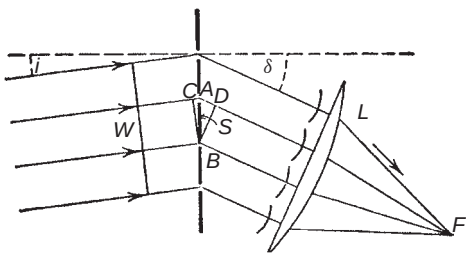

Fig. 1. Diffraction by a plane grating.

If the incident light is composed of various wavelengths, the corresponding images of any order will appear at different points, since δ varies with λ; and the result is a spectrum. In short, the grating acts as a dispersion piece, and as such is of great value in spectroscopes.

For high dispersion the slits must be very fine and very close together (S small), and for high resolving power (sharpness of spectral lines) the total number of slits must be large. Gratings having several thousand slits to the inch of width are common. They may be made by ruling fine scratches with a diamond point on glass, or, with reflecting gratings, on polished metal. If the rulings are not spaced with absolute regularity, false lines, called ghosts appear in the spectrum.

Rowland was the first to rule reflection gratings on concave metal surfaces. Such gratings eliminate the necessity of the spectroscope collimator or focusing lenses, as they take light direct from the spectroscope slit and form the spectral-line images like a concave mirror. The echelon is another special type of grating.

For a constant angle of incidence, the angular dispersion is given by

$$\frac{d\delta}{d\lambda} = \frac{n}{S\cos\delta}$$

and for small angles from the normal to the grating, cos δ may be replaced by unity. At the point of focus, usually a photographic plate, the so-called normal spectrum will have a constant linear dispersion, often expressed in mm per angstrom. The resolving power of a grating equals nN, where N is the total number of slits. It, too, is there a constant. For a prism spectroscope both dispersion and resolving power depend on the wavelength of the incident light. The constancy of these two quantities is thus an advantage for a grating instrument.

Typical gratings for the visible and the ultraviolet regions have 6,000–18,000 lines per centimeter, for the infrared, 700–3,000 lines per centimeter. These numbers are roughly equal to the wave number of the light to be dispersed.

For some other special kinds of gratings. See also **Echelette**; **Echelle Grating**; **Echelon**; and **Interferometer**.

DIFFUSE CHARACTERISTICS. Proceeding in all directions, not in any sharply defined path, as in the cases of diffuse reflection, diffuse refraction, and diffuse transmission of radiation.

DIFFUSER. A diffuser is a passage so shaped that it will change the characteristics of a fluid flow from a certain pressure and velocity to a lower velocity and a higher pressure. The diffusion must be carried out in a well-streamlined passage having smooth interior surfaces, and sides not diverging at so great an angle as to cause the fluid to leave the sides of the diffusing chamber. By reducing the velocity through increasing the cross-sectional area of flow, the pressure may be built up as the velocity head is diminished. Diffusers are applied to centrifugal fans, centrifugal pumps, jet pumps, centrifugal compressors, wind tunnels, and other equipment where it is required to conserve energy by efficiently converting velocity head into pressure.

DIFFUSE SKY RADIATION. Solar radiation reaching the Earth's surface after having been scattered from the direct solar beam by molecules or suspensoids in the atmosphere. Also called *skylight, diffuse skylight,* and *sky radiation*. Of the total light removed from the direct solar beam by scattering in the atmosphere (approximately 25 percent of the incident radiation), about two-thirds ultimately reaches the earth as diffuse sky radiation.

DIFFUSION. This term denotes the process by which molecules or other particles intermingle as a result of their random thermal motion. The molecules of a gas or of a liquid wander about rapidly, colliding frequently and exchanging kinetic energy, but maintaining a certain aimless progress. If an enclosure contains two gases, the lighter initially above and the heavier below, the gases at once begin to mingle because of their molecular motion. The same is true of a dense solution (as of sugar) and pure water; both the sugar and the water molecules wander across the boundary, so that in the course of time the whole body of liquid attains nearly uniform concentration. The process whereby this is effected is called diffusion. In the case of fluids of different color, its progress may be easily watched.

The rates at which different gases diffuse at a given temperature are inversely proportional to the square roots of their molecular weights. Thus, hydrogen diffuses four times as fast as oxygen. This follows, according to the kinetic theory, from the fact that the molecules of various kinds have the same mean kinetic energy and hence their mean square speeds are in the inverse ratio of their masses. In the case of a solution of non-uniform concentration, the diffusion of the solute from the more to the less concentrated regions takes place in accordance with *Fick's law*, expressed by the equation

$$\frac{dm}{dt} = -DS\frac{dc}{dx}$$

This gives the mass of solute diffused per unit time through a cross-section S, in terms of the concentration gradient dc/dx in the direction x perpendicular to the cross section. D is a constant for the given solute and solvent at a given temperature, and is called the diffusion coefficient. For any one pair of substances, D is found to be proportional to the absolute temperature. It should be stated that these statements apply only to nonelectrolytic solutions.

Diffusion in solids is a phenomenon that occurs rather slowly, but can be observed. Three basic processes may be responsible: (a) direct exchange of atoms on neighboring sites; (b) migration of interstitial atoms; (c) diffusion of vacancies. The first process requires very large energy. The energy to make an interstitial migration is rather large, but many atoms migrate easily. Vacancies are fairly readily formed, and diffuse fairly easily. From the Kirkendall effect it appears that (b) and (c) are the usual processes. The diffusion coefficient is related to the ionic mobility by the Einstein relation.

Another use of the term diffusion is to denote the passage of particles through matter in such circumstances that the probability of scattering is large compared with that of leakage or absorption. It is often limited to phenomena described by a member of the class of differential equations known as diffusion equations.

Diffusion operations are of large importance in chemical and process engineering. Both gaseous and thermal diffusion are used to separate one gas from another. In the case of *gaseous diffusion*, if a binary gaseous mixture at a high pressure is passed over a microporous barrier, a fraction of the gas will diffuse through the barrier into a low-pressure discharge chamber and will be found to be richer in the content of one gas than of the other gas. This is termed *Knudsen diffusion*. The passage of gas mixtures through the barrier is governed by the unequal collision frequency of each molecular species upon the walls of the pores. Fast, so-called light molecules separate from slower, heavier molecules within the barrier. The Oak Ridge, Tennessee plant designed for the enrichment of $^{235}UF_6$ from the naturally occurring uranium hexafluoride that contained 99.3% $^{238}UF_6$ represented the first major application of gaseous diffusion on a large scale. The molecular weight of the hexafluoride of ^{235}U is 349, whereas that of the hexafluoride of ^{238}U is 352. Inasmuch as the rate of diffusion of a gas is inversely proportional to the square root of density, the greatest separation factor for one stage of separation is the square root of 352/349, or 1.0043. Inasmuch as only part of the gas can diffuse through a given barrier, the separation factor is less. Thus, the number of diffusion stages for the Oak Ridge plant was approximately 4,000, requiring a plant that covered several acres of ground. Polymeric barriers also are under study and with scientific improvements, gaseous diffusion may become a widely used means for the recovery of carbon dioxide, helium, and nitrogen from natural gas.

In *thermal diffusion*, a thermal gradient is applied to a homogeneous solution (gas or liquid). This causes a concentration gradient and thus affords a means of separating materials. The logic of thermal diffusion is derived from the kinetic theory of gases and the cage model of liquids. If there is no marked size difference, heavier species tend to concentrate in the cold region. Where materials of identical molecular weight are involved, the larger molecules go to the cold region by virtue of their greater momentum. In the static mode, differential concentration can be established by eliminating convection currents that otherwise would tend to negate the effects of the applied thermal gradient. In the reflux method, hot and cold materials are flowed countercurrently. The reflux usually is provided using the density gradient that results from the imposition of the temperature gradient. Equipment of this latter type usually is referred to as a *thermogravitational column*, or a *Clausius-Dickel* column. Limited applications of thermal diffusion separations include those for concentrating dilute mixtures of isotopic gases. However, equipment costs tend to be high and efficiencies low.

Because chemical processing involves both the mingling and separating of fluids (gases and liquids), an understanding of diffusion processes is fundamental to process design.

DIFFUSION ANALYSIS. The determination of the relative size or molecular weight of particles by comparing their diffusion rates, or by separating them by differential diffusion methods.

DIFFUSION COEFFICIENT (or Coefficient of Diffusion). A measure of the rate of diffusion of a property, appearing as the factor K in the diffusion equation

$$\frac{\partial q}{\partial t} = K\nabla^2 q$$

where q is the property diffused, and ∇^2 is the Laplacian operator. The diffusivity has dimensions of a length times a velocity; it varies with the property diffused, and for any given property it may be considered a constant or a function of temperature, space, etc., depending on the context.

The most common diffusion process is that for which mass is the property diffused, and hence the differential in the equation can be expressed in terms of concentration change.

DIFFUSION CURRENT. The limiting current reached by electrolytic migration of the ions in a solution under the application of a potential difference to the electrodes. As the potential difference is increased the ion current to the electrodes increases rapidly at first but soon reaches a limiting value (the diffusion current value) as the potential difference is increased. If the potential difference is increased still further, a point is ultimately reached at which a new ion species begins to discharge.

The current limit is set by the rate of diffusion (of the ion being discharged) through the depleted layer surrounding the electrode. This diffusion rate is proportional to the ion concentration. For application of this effect, see **Polarographic Analyzers**.

DIFFUSION DENUDER TECHNIQUE. A technique for stripping a certain molecule or class of molecules from an airstream. The molecules of interest diffuse to the walls of a flow-through reactor, and are deposited there, while particulate matter passes through the reactor unchanged. The reactors are usually cylindrical or annular tubes, to maximize the surface area for a given volume, and the inner walls can be coated with chemicals to remove the molecules of interest, for example, citric or oxalic acid for ammonia removal. At the end of a given time the chemicals of interest are removed from inside the denuder for quantitative chemical analysis.

DIFFUSION EQUATION (Einstein). An equation for the mean square displacement of spherical colloidal particles in a gas or liquid, due to Brownian movement. The mean square displacement from their original position after a time τ is

$$x^2 = \frac{RT}{3\pi\eta r N}\tau$$

where R is the gas constant, T is the absolute temperature, r is the radius of the particle, η is the viscosity, N is Avogadro's number. This relationship is only valid for particles of such size that they obey Stokes' resistance law.

DIFFUSION LAYER. A layer of solution, actually a double layer, that is in immediate contact with an electrode during electrolysis.

DIFFUSION POTENTIAL. When liquid junctions exist where two electrolytic solutions are in contact, as in the case of two solutions of different concentrations of the same electrolyte, diffusion of ions occurs between the solutions, and the differences in rates of diffusion of different ions set up an electrical double layer, having a difference of potential, known as the diffusion potential or liquid junction potential.

DIFFUSIVE EQUILIBRIUM. The steady state resulting from the diffusion process, also known as gravitational equilibrium. In such a state the constituent gases of the atmosphere would be distributed independently of each other, the heavier decreasing more rapidly with height than the lighter. However, the occurrence of turbulent mixing precludes establishment of diffusive equilibrium.

See also **Isothermal Equilibrium**.

DIFLUENCE. The rate at which adjacent flow is diverging along an axis oriented normal to the flow at the point in question; the opposite of confluence. The difluence may be measured by

$$\frac{\partial v_n}{\partial_n} \text{ or } V\frac{\partial \psi}{\partial n}$$

where V is the speed of the wind, the n axis is oriented 90 degrees clockwise from the direction of the wind vector, v_n is the wind component in the n direction, and ψ is the wind direction measured in degrees clockwise from a reference direction.

DIGESTER (Process). In the process industries, the term *digester* is used in two principal connections: (1) the digestion of wood chips in the production of pulp prior to the manufacture of paper, and (2) the digestion of sewage sludge in waste-treatment operations. The term also appears in a number of other operations operating under varying conditions and hence a generalized definition is difficult to formulate. In chip digestion (also termed cooking), the chip digester is a large vessel provided with suitable raw-chip feed and cooked-chip discharge ports and equipped with means for heating and maintaining its contents at a specified temperature for a specific time. Batch digesters are vertical, stationary cylindrical pressure vessels into which chips and cooking liquor are charged and in which liquor is constantly moved, either by percolation within the digesters aided by direct addition of steam for heating purposes, or by continual withdrawal of liquor through screened ports and reintroduction of the liquor, after further heating. Modern batch digesters are typically 4,000 to 6,000 cubic feet (113.3 to 170 cubic meters) in volume with pulp capacities of 10 to 20 tons (9 to 18 metric tons).

By contrast in terms of operating parameters, sewage sludge is digested by aerating a lagoon or pond under normal outdoor temperatures, except that below about 40 °F (4.5 °C), the activity of the bio-organisms which aid in the digestion falls off considerably.

Autoclaves used in the chemical industry also are sometimes referred to as digesters.

DIGESTION. (1) The physiological processes involved in the assimilation of nutrients from ingested foods by the animal organism. Hydrochloric acid in the gastric juice plays a prominent part, aided by the saliva which initiates carbohydrate breakdown, and bile and pancreatic secretions in the intestine. Numerous types of enzymes catalyze these processes. (2) In chemical engineering, the term refers to several processes: (a) the preferential dissolution of certain mineral constituents in some ore concentrates, (b) the liquefaction of organic waste materials by microbiological action as the activated sludge, (c) the removal of lignin from wood by hot chemical solutions in the manufacture of chemical cellulose and paper pulp, (d) the separation of fabric from scrap tires by hot sodium hydroxide solution in the reclaiming of rubber. The equipment for (c) and (d) is called a digester.

DIGESTIVE SYSTEM (Human). The aggregation of organs concerned with ingestion, digestion, and elimination. Digestion may be defined as the complex physiological and chemical process for converting foods to forms that can be assimilated by the body cells. Since the food a person eats must be divided among the billions of cells of the body, it necessarily must be broken down to very small pieces. To accomplish this, the human body has a thorough digestive system which not only grinds the food mechanically, but breaks it up chemically into exceedingly small particles. See Fig. 1. The circulatory system is then responsible for distribution of the food among the individual body cells.

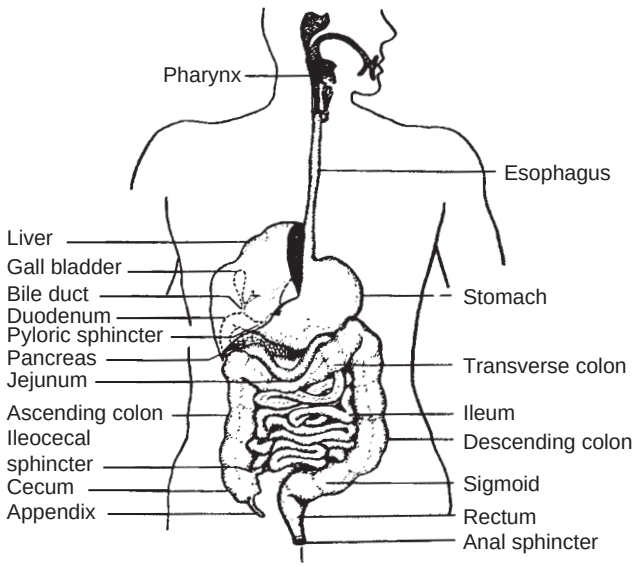

Fig. 1. The human digestive tract. A part of the liver has been cut away to show the stomach lying beneath it.

Digestion is aided by the way food is prepared. Cutting food finely and cooking it may accomplish some of the same steps toward digestion that the body would have to perform. For this reason, proper and adequate food preparation is important for babies as well as for older people whose natural digestive processes cannot take care of all the food they eat.

The body commences its work of digestion as soon as food enters the mouth. The mouth is the front end of a long tube (*alimentary canal*) which extends through the trunk of the body. Foods entering this tube are worked into proper form as they pass along it, and the unusable part of the intake is finally excreted from the other end of the tube, the anus. It is in this sense that the body can be considered as hollow, since the material in the digestive tract is not truly in the body tissue. Large numbers of bacteria live in certain parts of the digestive tube without disturbing the body in any way because they are outside the body tissues.

The teeth are arranged to grind food into small pieces. Along with the grinding action, the food is mixed thoroughly with saliva in the mouth. A mass of masticated food within the mouth or alimentary canal is known as a *bolus*. The saliva begins at once to digest the bolus of food by means of an enzyme in it (*ptyalin*) which breaks down the relatively large starch particles, as found in bread and potatoes, into much smaller pieces. The saliva swallowed with the food continues to act on the starch even after the food reaches the stomach. The saliva, in moistening the food, also makes it easier to swallow. When food is swallowed, it takes about 12 seconds for it to reach the stomach. Water and other fluids, however, may reach the stomach in as little time as 1 second, and may pass rapidly through it. Once in the stomach, the food is subjected to the action of the digestive juice which is formed by the stomach lining (*gastric juice*). This juice contains hydrochloric acid and a number of other more complex substances (enzymes) which start changing the food into simpler chemical materials. The most important of these enzymes is *pepsin*, which stimulates the breakdown of proteins into amino acids. The digestive juice oozes from the cells lining the stomach, while at the same time the stomach muscles contract and stretch, causing its shape to change constantly. This churning of the food may break up larger pieces of food, but its most important function is the proper mixing of the food with the digestive juices. Milk is a liquid which would pass immediately through the stomach were it not that the gastric juice contains an enzyme (*rennin*) that stimulates its coagulation or solidification. Consequently, the milk also may be digested in the stomach. Rennin, prepared from the stomachs of farm animals, is used to coagulate milk as the first step in making cheese.

When the food passes into the first 12 inches (0.3 meter) of the intestines (the *duodenum*), it is further broken down by duodenal digestive juices into exceedingly small, submicroscopic particles. The digestive secretions of the intestine are quite alkaline, as contrasted with the highly acidic juices of the stomach. If the food were not thoroughly chewed, the inside of the larger pieces of food could not be reached by the digestive juices of the stomach or intestine. Such pieces of food are not digested and are lost in the feces.

The digestive juices of the intestine come only partially from the cells lining the stomach. Much of the work is done by fluids or digestive juices made in other organs of the body, and carried to the intestine by special tubes or ducts. The bile duct, for example, brings bile from the liver, which aids in the digestion of fatty materials. The pancreas is another organ that manufactures digestive juices, and these are sent to the intestine by means of the pancreatic duct. The pancreatic juice is probably the most important of all the digestive juices because it completes the digestive process. It contains starch-digesting enzymes (*amylases*), fat-digesting enzymes (*lipases*), and protein-digesting enzymes (*proteases*). The pancreatic juice also contains the enzymes *trypsin* and *chymotrypsin* which digest proteins; *lactase* which digests lactose (milk sugar); and *steapsin* which digests fats. Actually, there are many other ingredients in the various digestive juices and the biochemistry is quite complex.

Not all the food that is eaten can be digested. The indigestible part continues to move along the length of the intestine. As this mass travels, large amounts of water which have been drunk or have come from the digestive juices are absorbed from it, and it assumes a firmer consistency. The lower part of the intestine is filled with billions of bacteria, which, far from being harmful, are extremely valuable. As they grow and reproduce, using the body's waste for food, these bacteria manufacture considerable amounts of vitamins. These vitamins are cast off by the bacteria and are absorbed into the body in pure form. Newborn babies may have a serious vitamin K deficiency during the first few days of life because some time is required for the bacteria to become established in their intestines.

The organs of digestion are not completely mature until the child reaches sexual maturity (puberty). The young child requires a diet consisting largely of mildly seasoned, easily digested foods. The capacity of children's stomachs is small and consequently periods of hunger are more frequent than in adults. Light, in-between-meal snacks are definitely of benefit.

Late premature infants (born 34 to 37 weeks from conception) can swallow, and may be fed from a nursing bottle supplied with a special nipple having a small bulb. Such infants also may be fed by means of a medicine dropper with a piece of rubber tubing attached. The tube is placed in the infant's mouth, and the milk is expressed slowly through the tube. Premature babies who cannot swallow often are fed through a rubber tube (catheter) attached to the barrel of a glass syringe. This method of feeding requires training and skill, for the tube is passed directly into the stomach.

Salivary Glands

Saliva is secreted into the mouth from three paired glands: the *parotid*, *submaxillary*, and *sublingual* glands. There are also numerous small salivary glands of the cheek and tongue. The parotid lies on the side of the face below and in front of the ear. The salivary secretions of the gland reach the mouth through a duct that runs inward through the fat of the cheek and opens on the inner surface of the cheek at the levels of the crown of the second molar tooth. The saliva secreted by the parotid is thin and watery. Secretion from the sublingual gland is thick and viscid, although the sublingual is the smallest of the main salivary glands. The gland rests immediately below the mucous membrane of the floor of the mouth, beneath the tongue. Its ducts open into the floor of the mouth through small conical elevations (*papillae*), which can be seen by the naked eye.

The submaxillary gland can produce either thick or thin saliva. It can be felt against the inside edge of the lower jaw. A long duct, about 2 inches (5 centimeters) in length, carries the saliva from the submaxillary gland to the floor of the mouth. Secretion of the salivary glands is under control of the nervous system. Stimulation of the body's glands may be by means of nerve impulses or by hormones, the latter form prevailing when rapid

response is not essential. Because food remains in the mouth for such a short time, the salivary glands are stimulated by nervous mechanisms. Food placed in the mouth causes a secretion of saliva within 2 to 3 seconds by an unconditioned or inherent reflex. A dry biscuit produces a thin water saliva, while a piece of meat causes a highly viscous saliva which lubricates the meat and enables it to be swallowed easily.

Pharynx and Esophagus

The pharynx is the vertical passage beginning behind the nose and mouth and extending from the base of the skull above to the esophagus below. See accompanying diagram. The pharynx is equipped with three semicircular muscles located one under the other which enable the pharynx to squeeze food down toward the esophagus. One of the most muscular parts of the digestive system is the esophagus. It is a flattened tube passing through the lower part of the neck, the whole length of the chest, and joining the stomach just below the diaphragm. The esophagus is 10 to 12 inches long in the adult. Normally, the entrance into the stomach is kept closed by a muscular contraction in the lower inch or so of the esophagus, which opens as a piece of food approaches, but prevents reflux of acid from the stomach to the esophagus.

The Stomach

This organ is a receptacle in which food accumulates. Some of the earlier processes of digestion take place here, namely, the conversion of food into a viscous fluid. The normal stomach is J-shaped, with a bulge above and to the left of the junction with the esophagus. The shape varies according to whether the person is standing, sitting, or lying down; and according to whether the stomach is full or empty. The stomach lies in the upper left portion of the abdomen, its long axis being nearly horizontal. The stomach narrows to join the small intestine forming a canal (the *pyloric canal*), which has a thick muscular valve (the *pyloric sphincter*). This sphincter remains closed so long as the food in the stomach is solid. The pyloric sphincter relaxes only when the gastric contents have been changed into a semifluid state. If only liquids are taken into the stomach, the pylorus opens and the fluid passes into the small intestine almost immediately. Usually it takes from 3 to 4 hours or somewhat longer before the stomach completely empties a meal into the small intestine. Minute glands in the stomach manufacture hydrochloric acid and certain ferments, which break down portions of the food into simpler substances. The muscular coats of the stomach grind and mix the food with the stomach secretions. The physical grinding and crushing is of great importance in normal digestion.

The Bowel

Intestines, the portions of the digestive system from the stomach to the anus, are divided into two main parts, the *small intestine* and the *large intestine*. The small intestine begins at the pyloric sphincter and lies in the abdomen in coiled loops. It is 20 to 22 feet (6 to 6.7 meters) long. Thus, the small intestine occupies the greater portion of the abdominal cavity. It gradually diminishes in size as it extends downward, having a diameter of about 2 inches (5 centimeters) where it joins the stomach, and about 1 inch where it joins the large intestine. The first portion of the small intestine is called the *duodenum*, which is about 8 to 10 inches (20 to 25 centimeters) in length. The duodenum differs from the remainder of the small intestine in that it is fixed to the posterior abdominal wall. The ducts of the liver and pancreas open into the duodenum. The remaining small intestine is divided into the *jejunum* and the *ileum*. The upper 8 feet (2.4 meters) of the small intestine, after the duodenum, is regarded as the jejunum; the lower 12 feet (3.6 meters) as the ileum. The coils of the small intestine are able to move about freely in the abdominal cavity, being connected to the posterior abdominal wall by a fan-shaped sheet of tissue (the *mesentery*), which measures about 20 feet (6 meters) at its free edge and only 5 or 7 inches (12.5 or 17.8 centimeters) at the attachment to the abdomen. The blood vessels, lymph vessels, and nerves serving the intestine lie between the layers of this sheet of tissue.

The piece of food (*bolus*) travels along the small intestine in a series of rushes; the bowel contracts just behind the bolus and relaxes in front of it. This contraction and relaxation occurs in a series of alternating wavelike motions, known as *peristaltic movement*. There are also regular constricting movements of the intestine which occur at a rate of 20 to 30 per minute, kneading the food thoroughly and insuring that the digestive juices are well mixed with it.

The small intestine opens obliquely into the large intestine. A valve (*ileocecal valve*) is located at the junction. The valve permits the passage of the contents of the small intestine into the large intestine, at intervals. It also prevents the return of material into the ileum.

The large intestine begins on the right side of the abdomen just above the rim of the pelvis, and is about 5 feet (1.5 meters) long. Arranged in an inverted horseshoe shape around the small intestine and about 3 inches (7.5 centimeters) in diameter at its commencement, the large intestine gradually narrows to the anus. The large intestine is divided into: the cecum and vermiform appendix; the ascending colon; right flexure of the colon, transverse colon, left flexure, descending colon, sigmoid colon, rectum, and anal canal.

The *cecum* is that portion of the large bowel that hangs below the opening of the ileocecal valve. It is a blind sac to which is attached a worm-like tube, the *vermiform appendix*. The appendix usually is about 3 inches (7.5 centimeters) long, but may be as long as 9 inches (22.9 centimeters) or as short as 1 inch (2.5 centimeters).

The nearly fluid contents of the ileum pass through the ileocecal valve and collect in the cecum. Slowly the contents are forced up into the *ascending colon*. Movement through the large intestine is slow and takes place in periodic rushes. In order to reach the outside of the body, it is necessary for the large intestine or bowel to penetrate the floor of the pelvis. At this juncture, the large bowel is enclosed by two muscles, the internal and external sphincters, which compress the sides of the tube and reduce its cavity to a narrow passage. That part of the large intestine immediately preceding the muscles is termed the *rectum*. The terminal portion of the passage, from the rectum to the external opening or *anus*, is called the *anal canal*. The sphincters remain closed except during defecation. These muscles are voluntary muscles. The waste material of digestion deposited in the rectum is known as *feces* or *fecal matter*. Most of the time the rectum is empty. When the colon becomes full, the fecal matter passes into the rectum. The desire to defecate is a reflex initiated by pressure on the walls of the rectum by the feces.

Absorption of food is effected almost entirely in the small intestine. The large intestine secretes some material and absorbs water, so that the amount of material finally excreted is only about one-third of the weight of material entering. Most of the absorption of fluid takes place in the cecum and ascending colon. The color and odor of the feces are caused by the action of bacteria, which inhabit the large bowel, and by the pigments present in the bile. During starvation, feces continue to be formed from bile, which is emptied into the digestive tract from the liver, and from bacteria and other secretions from the bowel itself.

DIGESTIVE SYSTEM (Other Life Forms). One-celled animals and sponges take food into the cell to be transformed by a process of intracellular digestion. While this process persists to a limited extent in coelenterates, flatworms, and mollusks (*Mollusca*), these and all other animals also have some form of digestive system or alimentary tract in which food is retained for extracellular digestion preceding absorption. Secretions are discharged into this tract by the cells of its lining and are mixed with the food. The cavity is lined with endodermal tissue, in many cases supplemented by ectodermal ingrowths at both ends.

The simplest form of digestive system is the enteric cavity of coelenterate polyps. It is little more than a sac with one opening through which food enters and undigested wastes are discharged. In the flatworms a similar condition prevails, but in both the jellyfishes and in some flatworms the cavity is complex, extending throughout the body in a system of canals or branches which distribute the food as well as absorb it. From the roundworms through the remainder of the animal kingdom the system is tubular, opening at one end by the mouth and at the other by the anus.

In the tubular digestive tract, specialization of digestion reaches a maximum. Here, food passes, by the muscular movement of the walls, successively through different regions instead of being mixed indiscriminately, hence each region may subject it to special treatment. The chief regions are those which aid in securing food, simple passages, storage reservoirs, grinding structures, and digestive regions which include chambers and tubular regions which may be long, narrow and coiled with the inner surface thrown into folds or minute finger-like processes (villi) to increase the area of contact. In addition, glandular derivatives of the lining are so highly developed that they become separate organs associated with the tubular tract by slender ducts.

Some of the worms have a very simple tract with a muscular pharynx that aids in securing food and a long simple intestine, in which it is digested. Other animals, including the leeches, insects, and birds, have a crop in which food is stored prior to digestion. The mastax of rotifers and the gizzard of birds are examples of grinding structures.

The mammalian alimentary tract is a good example of regional specialization. The oral cavity, with its teeth, provides for chewing and some digestion; the pharynx and oesophagus furnish a passage to the stomach, where food is stored and slightly digested; the small intestine completes digestion and absorbs the end-products; the large intestine absorbs water; and the rectum stores the remaining wastes for periodical discharge by way of the anus. Glands associated with this tract are the salivary glands, the liver, and the pancreas.

DIGESTIVE SYSTEM (Ruminants). Bovines (cows, buffalos, oxen), goats, sheep, antelopes, deer, camels, and chevrotains, among others, possess a unique digestive system which enables them to convert many coarse, fibrous plant products, wastes, and byproducts into high-quality feed. These animals can process materials that otherwise would be wasted entirely or returned to the soil. In contrast with the stomach of humans and most other mammals, the corresponding portion of the digestive system of ruminants is relatively large and is divided into four major compartments, as shown in Fig. 1.

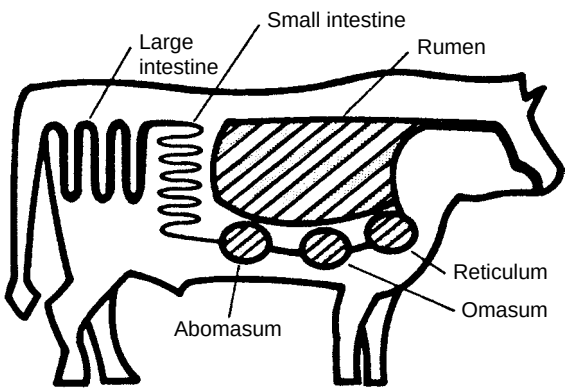

Fig. 1. Highly schematic representation of digestive system of a ruminant, showing the four distinct chambers of the stomach: Rumen, reticulum, omasum, and abomasum.

Ruminants are endowed with control devices that provide both the environment required for rapid microbial action and the time needed for bacteria to digest the cellulose, proteins, and other organic constituents in the plant substances eaten. Cellulose is the most abundant chemical component of plants and is the most abundant organic chemical substance on earth. Cellulose, indigestible by humans, is digested by ruminants to the extent of 30–80%. The products, chiefly simple fatty acids, are directly absorbed by the animal during the microbial breakdown of the plant materials. These fatty acids provide the animal with most of its dietary energy.

At the same time, the microorganisms use the chemical fragments produced from the plant material to synthesize microbial substance containing high-quality proteins and vitamins. The microorganisms synthesize all the essential amino acids needed by humans. The same microorganisms also synthesize other substances essential to the human diet, including all B-complex vitamins and vitamin K.

When a ruminant swallows vegetation or other substances, the material is only partially chewed. The material first goes into the *rumen* (1st stomach or paunch), which performs a number of functions. The rumen chamber, which in a large mature cow may have a capacity of up to 300 pounds (136 kilograms), acts as a storage chamber while the animal continues with its feeding. Between periods of browsing, the animal will ruminate, considered by authorities as a very pleasurable period for the animal. During this period, large pieces of feed material will be regurgitated, an action similar to vomiting, but without any unpleasant sensations to the animal. These larger pieces are more finely ground by the animal by the chewing action of the mouth (chewing the cud). The rumen also preprocesses the food so that bacteria present can assist with a massive breakdown of the food and preparing it for later action by gastric juices. The bacterial action essentially is one of fermentation. Introduction of saliva into the rumen assists in controlling the pH of the rumen. Depending upon the type of feed consumed, there will be a variety of microbial flora — bacteria, yeasts, protozoa — present in the rumen to participate in the biochemical reduction of the feed. During this process, crude fibers are conditioned for further digestive action, essential amino acids and complete proteins are created, and B-complex and K vitamins are produced. During fermentation, significant quantities of gaseous carbon dioxide, methane, and ammonia, and small quantities of hydrogen sulfide and carbon monoxide, are formed. The presence of these gases is relieved by a reflex action of belching, but in some cases, the buildup of gases causes a condition known as *bloat*. This can be a serious condition.

The *reticulum* (2nd stomach or honeycomb) is not fully separated from the rumen. Actually, materials can pass freely from one chamber to the next. The reticulum is named for its folds, forming hexagons (the pattern noted on tripe). A major function of the reticulum is to screen out foreign objects that would not later pass through the remaining stomachs and intestines. Husbandmen sometimes refer to the reticulum as the "hardware" stomach, because it is here that nails, bits of wire, large pebbles, etc., will be captured. Keeping in mind that the process involving the four stomach chambers is continuous, the preprocessed bulk from the rumen (some of which has been regurgitated and returned to the rumen a second time) passes quickly through the reticulum and on to the last two chambers of the stomach. The *omasum* (3rd stomach and also known as "manyplies" because of the presence of many plies or folds of tissue in the organ) functions to reduce the water content of the feedstuffs, as well as to provide additional grinding and squeezing actions on the feed. However, the complete role of the omasum is not fully understood. From the omasum, the material flows into the *abomasum* (4th stomach and sometimes referred to as the "true" stomach). This is called the true stomach because the abomasum acts very much like the stomach of monogastric mammals. Here, digestive juices are admixed with the stomach content and the moisture content is increased. Enzymatic juices in the abomasum aid in protein digestion. However, there is little if any digestion of fat, cellulose, or starch in the abomasum. The latter nutrients are digested and absorbed in the small intestine. As the feed and partially digested materials leave the abomasum, they are highly fluid.

In the last stage of the ruminant's digestion process, the digestive juices are used to break down the microorganisms. During the microbial digestion of the plant materials by the ruminant, the plant proteins are broken down and their nitrogen is released in the form of ammonium. The ammonium is absorbed by the microorganisms and used for producing new proteins. Knowledge of this mechanism has made it possible to increase the efficiency of ruminants in converting low-protein feed, such as cornstalks (maize), by supplementing the diet with synthetic urea, which the microorganisms decompose quickly with the release of ammonium. The artificially supplied ammonium then is absorbed by the microorganisms, like that derived from the plant proteins, to develop new microbial proteins. The cost of nitrogen in the form of urea is relatively low by comparison with the cost of nitrogen in the form of protein.

DIGIT (Computer System). A symbol used to convey a specific quantity either by itself or with other numbers of its set, e.g., 2, 3, 4, and 5 are digits. The base or radix must be specified and each digit's value assigned.

Binary Digit. A number in the binary scale of notation. This digit may be zero (0), or one (1). It may be equivalent to an "on" or an "off" condition, or to a "yes" or "no" condition. Often abbreviated *bit*.

Check Digit. One or more redundant digits carried along with a machine word and used in relation to the other digits in the word as a self-checking or error-detecting code to detect malfunctions of equipment in data transfer operations.

Equivalent Binary Digits. The number of binary positions needed to enumerate the elements of a specific set. In the case of a set with five elements, it will be found that three equivalent binary digits are needed to enumerate the five members of the set: 1, 10, 11, 100, and 101. Where a word consists of three decimal digits and a plus or minus sign, 1999 different combinations are possible. This set would require eleven equivalent binary digits in order to enumerate all of its elements.

Octal Digit. The symbol 0, 1, 2, 3, 4, 5, 6, or 7 used as a digit in the system of notation which uses 8 as the base or radix.

Sign Digit. A digit incorporating one to four binary bits which is associated with a data item for the purpose of denoting an algebraic sign. In most binary, word-organized computers, a 1-bit sign is used: $0 = +$ (plus); and $1 = -$ (minus). Although not strictly a digit by the above definition, it occupies the first digit position and it is common to consider it as a digit.

IBM Corporation, Boca Raton, FL

DIGITAL COMPUTER SYSTEMS. Initially, machines called digital computers were designed to calculate (compute) automatically the answers to (1) simple arithmetic problems (addition, subtraction, multiplication, etc.) and (2) more difficult mathematical problems involving simple and very complex equations of relationship. Over the years, the handling of millions and billions of calculations have been invaluable in scientific research.

To computer designers, it soon became evident that the design elements required to perform arithmetic and mathematical calculations also could be used to manipulate information in other ways, such as storing, retrieving, sorting, classifying, etc., and thus these other duties were added to the computer's computing capabilities.

If being named today, perhaps the computer would be called more properly an information machine, because the modern computer in a few comparatively short years has become a super information processing system, making possible the establishment of vast arrays of information networks. In perspective, the computer is becoming part of the communications "woodwork" so to speak.[1,2]

Although digital computers may be hydraulic, mechanical, electrochemical, or hybrid (analog/digital), the vast majority of digital computers are electronic.[3]

This article is divided roughly into three time frames: (1) Early history of digital computers — 3000 B.C. to the early 1960s; (2) Middle-age digital computers — mid-1950s to late 1980s; and (3) Modern and future digital computers (late 1980s to the year 2000 and beyond).

EARLY HISTORY OF DIGITAL COMPUTERS

(3000 B.C. to the Early 1960s)

Doubtless, the early cave people counted on the fingers, but no documentation for this can be found. As reported in the article on **Calculator (Abacus)**, records indicate that the first major improvement in finger or toe counting appeared as early as 3000 B.C., accrediting the Babylonians with its invention. The abacus became very popular in the Orient and, somewhat surprisingly, many numbers of them remain in use, notably in China. It is reported that a century or so ago, the British occasionally used checkered tablecloths for counting and it is alleged that the term British Exchequer was so derived.

In the year 1642, Blaise Pascal, the son of a French tax collector, invented the first mechanical-type calculating machine. The machine was operated by a stylus and had the ability to handle carryovers from one column to the next. Pascal called his invention, the *arithmetic machine*.

Nearly 200 years later, C.X. Thomas, also a Frenchman, brought into fruition a concept proposed by Gottfried Leibniz (Germany) and it was called the arithmometer. In addition to adding and subtracting, the machine could multiply and divide by using the concept of repeated addition and subtraction.

During this same general period, but with somewhat different intentions, Jacques de Vaucanson (France), in 1741, and somewhat later, Marie Jacquard (France), in 1804, used holes punched, first in metal drums and later in punched cards, as a control or programmer for textile looms.

An Englishman, Charles Babbage, in 1823 commenced construction on what he called a *difference machine*. This machine was based on the fact that an equation of degree n will have a constant nth difference. With the machine, Babbage made calculations for trigonometric and logarithmic tables. Babbage succeeded in constructing a machine that would solve a second degree equation. Babbage's more ambitious *analytical engine* equipped with a memory, control, an arithmetic unit, and an input/output section was abandoned because of difficulties in producing parts with sufficient precision to achieve intended results.

In a recent interesting article (See reference listed), D.D. Swade (Science Museum, London) describes how Babbage's mechanical computer has been reconstructed for display. Detailed plans, which Babbage had drawn up during the period 1847–1852, were used to construct an operating model for display. The redeemed design was put on display in a London museum in November 1991, one month prior to the bicentenary of Babbage's birth.

In a computer-related event, Herman Hollerith devised a punched card for use in counting and sorting tasks in connection with tabulating data from the 1890 census of the United States. The technique proved successful in reducing the time needed for obtaining results of the census from a formerly estimated 10 years to less than 3 years. Hollerith later revised the punched card and this became the so-called IBM card still used in punch card techniques. It has been suggested that Hollerith probably based his card design on the earlier punched card approaches used by Jacquard nearly a century earlier.

While the digital approach to computing was proceeding rather slowly during the 19th Century and early part of the 20th Century, progress was also being made with analog computers, of which the engineers' sliderule (mechanical analogy), and pneumatic and hydraulic calculating mechanisms were used in industrial automatic controllers. Some of these analog approaches remain, but largely have been replaced by digital computation.

The early analog computers of the type designed by Vannevar Bush and others in the 1930s followed some of Babbage's mechanical principles, but were soon displaced by the pioneering electronic techniques of the 1930s. This type of activity was probably culminated by the *Maddida*, a digital differential analyzer developed in 1949 at the Northrop Aircraft Corporation. The machine had 44 integrators implemented using a magnetic drum for storage. Addition was done serially. The drum had 6 tracks, one of which

[1] M. Weiser (Xerox Corporation) has made the interesting analogy of the modern computer with the industrial electric motor when it was introduced in the late 1800s. The motor was touted as a key prime mover of dozens of important individual machines in a workshop, whereas today motors are smaller, more efficient and, for example, as many as a score of individual electric motors may be used in a single motorcar.

[2] Only a relatively few years ago, the term *electronic data processing* (EDP) was used widely. EDP now appears only infrequently in the literature, have been shoved aside by the single word *computer*. The latter word, unfortunately, does not convey the fullness of meaning of what computers really are today.

[3] Analog computers operate on continuous variables, in the form of voltage or current (electrical analog of a physical quantity) that is continuously changing with time — in contrast with the step-like, digitalized input characteristic of digital computers. See **Analog Computer**.

was used for synchronization. The problem was specified by writing an appropriate pattern of bits onto one of the tracks. Because of competition from electronic approaches, the machine had a short useful life.

During the 1930s, recognition of the fact that electrical and electronic techniques were required to make practical, accurate computations of large quantities of data, as exemplified by the early scientific interest in solving equations and proving theories, was announced by a number of researchers. The foundations of computers were developed by a number of scientists, including George Boole and Allan Turing. Boole pioneered in the field of symbolic logic and his now famous Boolean algebra provided a mechanism for representing logic in mathematical symbols and rules for calculating the truth or falsity of statements. Digital computers, of course, carry out these operations an immense number of times at fantastic rates. Allan Turing hypothesized a universal computer and in a paper on "Computable Numbers" in 1936 described the hypothetical Turing machine that can solve any type of mathematical problem which can be reduced to coding in a given set of commands within the memory capacity of the machine. See article on **Turing Machine**.

The first application of Turing's principles was made by Bell Telephone Laboratories (now AT& T Bell Laboratories) in the form of a relay computer, announced in 1939. In 1944, the second significant relay computer, which also proved to be the first *general-purpose digital machine*, was built by Howard Aiken (Harvard University) with funds provided by IBM Corporation. The machine, a huge electromechanical calculator, was called the *Mark I*. The machine incorporated 72 decimal accumulators, capable of multiplying two 23-digit numbers in 6 seconds. The machine was controlled by a sequence of instructions from a perforated paper tape. The machine lacked general conditional jump facilities. It was known as the *Automatic Sequence Controlled Calculator*.

Essentially during the same time frame, Konrad Zuse (Germany) introduced the Z3 machine (1941). The Z3 had been preceded by two earlier, unsuccessful models. The machine had a mechanical store, but was otherwise constructed with telephone relays. The machine could store 64 floating-point binary numbers and was described as somewhat faster than the Mark I. The machine was destroyed during World War II. A fourth machine, however, was built and was used at the Technische Hochschule in Zurich, Switzerland for a number of years.

The first electronic computer (not solid state) was developed in 1946 by J.P. Eckert and J.W. Mauchly (Moore School of Electrical Engineering, University of Pennsylvania) with funds provided by the U.S. Army. The main purpose was that of calculating ballistic tables. Between 18,000 and 19,000 vacuum tubes replaced mechanical relays as switching elements. The machine weighing over 30 tons occupied a very large room. Large amounts of heat were generated by the tubes. The machine was not considered very reliable. The machine existed until 1955 and logged some 80,000 hours of operation. The machine was known as the *Electronic Numerical Integrator and Calculator* (ENIAC).

It is interesting to note that in the early years of machine development, the word computer did not appear in the naming of the machines.

Commencing essentially with the mid-1940s, digital computer development quickened its pace. IBM continued active in the field and, in 1947, produced the *Selective Sequence Electronic Calculator* (SSEC). The Moore School developed a follow-up of the ENIAC, known as the *Electronic Discrete Variable Computer* (EDVAC), which was unveiled in 1952. Most historians now accept the fact that the EDVAC was the first stored program computer. Unlike earlier machines which were programmed at least partially by setting switches or using patch boards, the EDVAC and all others to follow, stored instructions and data in identical fashion. EDVAC used acoustical delay lines, which were simply columns of mercury through which data passed at the speed of sound, as the main memory. This type of storage soon gave way to magnetic core memory, the antecedent of present semiconductor memory.

Computer Architecture Developments

In 1946, John Von Neumann, a mathematician at the Institute of Advanced Study, Princeton, New Jersey, prepared a paper on "Preliminary Discussion of the Logical Design of an Electronic Computing Instrument." The project, financed by the U.S. Army, suggested the principles of design for digital computers that were built during the next several decades. Principles outlined by Von Neumann included internal program storage, relocatable instructions, memory addressing, conditional transfer, parallel arithmetic, internal number base conversion, synchronous internal timing, simultaneous computing while doing input/output, and magnetic tape for external storage. A computer built along these lines actually went into operation in the early 1950s. UNIVAC (*Universal Automatic Computer*) was the first commercially available digital computer to use these principles. The UNIVAC was a descendent of ENIAC and EDVAC, having been built by Remington-Rand following acquisition of the Eckert-Mauchly Computer Corporation. Eventually, 48 UNIVACI's were built, making Remington Rand the number one computer manufacturer — until IBM commenced in earnest in 1954 with the introduction of its 700 line.

A few intervening developments of interest not previously mentioned included the EDSAC (*Electronic Delay Storage Automatic Calculator*), developed (1949) in Cambridge, England by W. Renwick and M.V. Wilkes; the Ferranti Mark I computer, developed (1951) at Manchester University; the Pilot ACE (*Automatic Computing Engine*), developed (1950) at Manchester University; the SEAC (*Standards Eastern Automatic Computer*), developed (1950) at the U.S. National Bureau of Standards; and the *Whirlwind I*, developed (1950) by J.W. Forrester at the Massachusetts Institute of Technology, among a few others. It is interesting to note that the SEAC used an ultrasonic memory, but a Williams[4] tube memory was later added for evaluation. This tube was also used by a few of the aforementioned early computers.

The characteristics of several of the early computers just mentioned are summarized briefly in Table 1.

MIDDLE-AGE DIGITAL COMPUTERS

(Mid-1950s to Late-1980s)

In the early period of very rapid expansion of computer applications, made possible by advances in semiconductor technology, computer architecture was based on the von Neumann model. Toward the late 1980s, newer concepts, from an applications standpoint, took digital computers into different and rather revolutionary directions, including pipelining and parallel processing.

Elements of a Traditional Digital Computer System

Basically, a digital computing system comprises input and output equipment for the physical handling of machine information and instructions, and a central unit which performs the electronic processing.[5]

Central Processing Unit (CPU). Sometimes referred to as the *main frame*, the CPU is that part of a digital computing system exclusive of input and output devices. The central unit typically is made up of one or more CPUs and their associated storage.[6] In large systems having more than one CPU, the term *central electronic complex* (CEC) may be used to describe the set of CPUs. The CPU, in turn, is made up of a control section, an arithmetic and logical unit (ALU), local storage (registers) and, in some large machines, a input/output (I/O) controller. The control section controls the step-by-step operation of the system by fetching instructions from the storage, interpreting them, and providing the necessary signals to effect control of the ALU and other portions of the system. See Figs. 1 and 2.

[4] The first stored-program computers relied for their memory either on ultrasonic delay lines (mercury tank), or the Williams tube, developed by F.C. Williams of Manchester University. This was a cathode-ray tube in which storage of information at a spot on the inside of the face of the CRT was determined by the relative charge level. As described by Wilkes in an early paper, the secondary emission ratio for phosphors (and for glass) is greater than one. Thus, if the face is bombarded with a primary electron beam of 1 to 2000 V acceleration, the spot becomes positively charged because more low-energy secondary electrons are emitted by the surface than arrived in the primary electron beam. Equilibrium is reached when the relatively positive charge of the spot attracts enough electrons to balance the flow. If the spot is charged, then the nearby area is "discharged" by the secondary electrons from the primary spot. Williams used the CRTs in a bit-serial mode.

[5] The descriptions in this section of the article are directed to the traditional computer design of a stand-alone nature as contrasted with the dissection of certain computer features which because of the opportunities of high density offered by LSI (large scale integration), VLSI (very large scale integration), ASIC (application-specific integration), etc. often become parts of minicomputers, microprocessors, and the like. Check alphabetical index.

[6] This description of the CPU and other major aspects of contemporary digital computers was furnished by T.J. Harrison, IBM Corporation, Boca Raton, Florida.

TABLE 1. CHARACTERISTICS OF EARLY DIGITAL COMPUTERS (Circa 1952)

Name	Serial (S)/ Parallel (P)	Decimal (D)/ Binary (B)	Number of Addresses	Word Length	Memory Type	Memory Words	Max. Memory Access (ms)	Number of Tubes	Number of Diodes	Input/ Output
EDVAC	S	B	$3+1^a$	44 bits	U	1024	0.38	3600	10,000	Paper tape
UNIVAC	S	D	1	12 char	U	1000	0.40	5600	18,000	Magn. tape
IAS	P	B	1	40 bits	W	1024	0.025	2300	0	Cards
EDSAC	S	B	1	35 bits	U	512	1.1	3800	0	Paper tape
Ferranti I	S	B	1	40 bits	W	256	0.64	3800	0	Paper tape
Pilot ACE	S	B	[a]	32 bits	U	360	1.0	800	—	Cards
SEAC	S	B	3	45 bits	U	512	0.38	1300	15,800	Paper tape
SWAC	P	B	4	36 bits	W	256	-	2300	3000	Paper tape/Cards
Whirlwind I	P	B	1	16 bits	E	256	0.016	6800	22,000	Paper tape
Harvard Mark III	S/P	D	3	16 dec.	D	4000[b]	4.5	5000	1300	Magn. tape
Burroughs	S	D	1 or $1+1^a$	9 dec.	D	800	32	3271	6773	Paper tape
ERA 1101	P	B	$1+1^a$	24 bits	D	16,384	17	2200	3000	Paper tape

[a] Provision for minimum-access coding.
[b] Separate 200-word memory for instructions.
U = Ultrasonic delay (mercury tank); W = Williams tube; D = Magnetic Drum; E = Electrostatic (CRT).
After: M.V. Wilkes (1976).

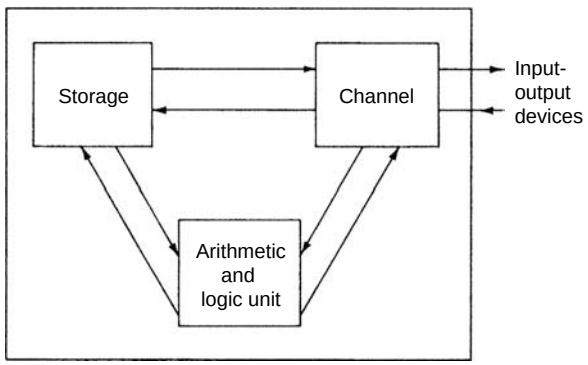

Fig. 1. Computer central processing unit (CPU).

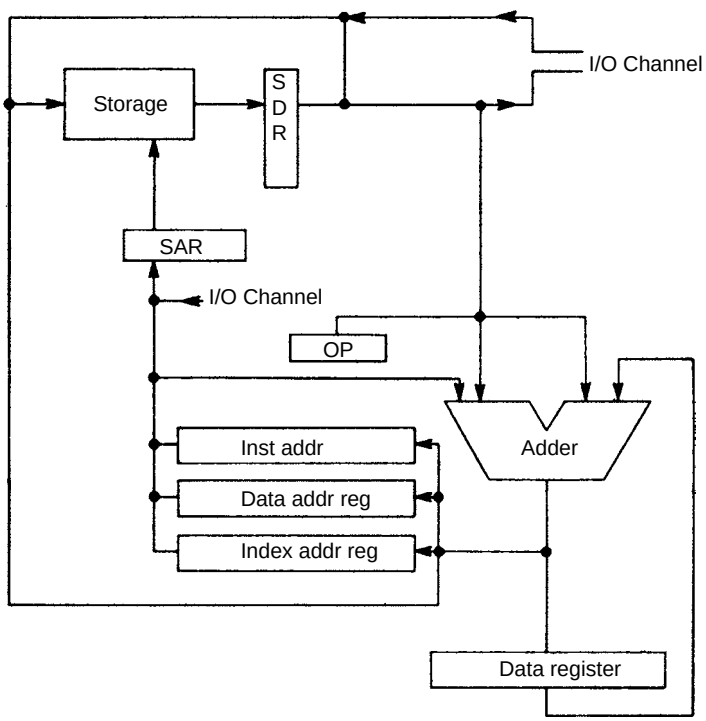

Fig. 2. Data flow in computer central processing unit.

If a separate channel controller is used, it provides the detailed control of information flow to and from the I/O units. In smaller systems where a separate channel controller is not used, this function is provided by the control sections of the CPU. Storage holds both the instructions to be executed, called the *program*, and the data to be processed. These are stored so that they are readily available when needed. Data and instructions also are stored on external storage devices, such as magnetic devices. The information stored on these devices is read into the main storage when needed. See also **Storage (Computer)**.

Actual processing of data is performed in the ALU according to the stored program instructions. Fundamentally, the ALU provides for comparison of two data items, arithmetic operations such as addition and subtraction, and logical operations such as AND and OR. However, most computers provide several hundred different instructions which are combinations of these fundamental operations. For example, a single instruction may be provided which will fetch two operands from storage locations, add them together, and store them in a third storage location. A very important class of instructions provides for altering the sequence of instructions based on the result of a calculation or comparison. For example, when comparing two numbers A and B, if A is less than or equal to B, the computer may "branch" or transfer control to a different set of instruction than if A is greater than B. This provides for handling alternatives in the solution of a problem and is the most significant difference between a computer and a calculator.

Input devices read data to be processed and programming instructions into the main storage unit or, sometimes, into the CPU itself. Common input devices include card readers, keyboards, magnetically encoded document readers, magnetic drum, disk, diskette, and tape units. Output devices transcribe processed data into machine media such as tape, disk, or cards, and to devices providing human-readable information such as cathode ray tube (CRT) displays and printers.

The computer also may accept input from, or provide output to, another computer. When two or more computers are interconnected in this fashion, are in close physical proximity (usually), and cooperatively participate in the solution of a single problem, the aggregate of computers often is referred to as a *multiprocessor*. The interconnection between the computers is by a channel-to-channel link or similar means to allow high speed interchange of information. Also, typically, a single control program directs the operation of the interconnected computers.

A related concept, sometimes called *distributed processing* or *computer networking* also involves interconnected computers. Although precise definitions do not exist, computer networks generally involve two or more computers which are geographically separated and interconnected by serial communication facilities such as telephone lines or dedicated coaxial cable. Information is interchanged between the computers, generally at a rate much slower than in the case of the multiprocessor. The computers in a network generally are under the control of individual, autonomous control programs so that cooperation is effected in a manner similar to a peer group of individuals.

Distributed processing may involve computers interconnected either by slow-speed communication facilities or by high-speed channel-to-channel connections. Distributed processing usually implies, however, that the interconnected processors work cooperatively on the *same* problem (as

in the case of the multiprocessor) but not necessarily under control of a single control program; that is, the involved computers are at least semi-autonomous. The reader is cautioned that the distinction between these terms is not clearly defined at the present time, since the concepts of distributed processing and computer networks are just beginning to be widely implemented.

Computer Hardware

The computer *hardware* is the physical equipment that comprises a computer system. This is to be contrasted with the *software*, which is the aggregate of the programs, procedures, and, sometimes, documentation which is necessary to use the hardware effectively. Taken together, the hardware and the software represent the computer system; it is not uncommon, however, to find the term "system" used in reference to only the hardware. The basic structure and cyclical operation of the computer has remained essentially unchanged since the invention of the early electromechanical and electronic computers in the 1940s. The basic sequence of operations is: (1) fetch an instruction from storage; (2) decode (interpret) the instruction to determine the operation to be performed and the location of the operand(s); (3) fetch the operands from storage, if necessary; (4) perform the operation on the operand(s); and (5) fetch the next instruction from storage. There often is considerable data manipulation during each of these basic steps. For example, fetching operands from storage may require arithmetic operations to calculate the physical storage location from a relative address provided in the instruction.

The basic speed of the computer is determined by the characteristics of the circuits used to build the hardware. However, and particularly in high performance machines, a number of techniques are used to increase the effective processing speed beyond the limits imposed by circuit speed. One method is to overlap the basic steps outlined above. As one example, unless the location of the next instruction depends on the outcome of the current operation, it is possible to overlap the operation (step 4) and the fetching of the next instruction (step 5). Another technique, called pipelining, utilizes a series of processing subsystems to operate on several instructions concurrently. For example, during the cycle in which the operation specified in instruction n is being executed, a separate processing unit is calculating the effective or physical address need for instruction $n+1$, while yet a third processing unit is fetching instruction $n+2$. Occasionally, the instructions being preprocessed ($n+1$ and $n+2$) need to be "thrown away" since instruction n causes a branch to an instruction other than $n+1$. On the average, however, a decrease in total processing time is effected by the concurrent operation.

It is also common to provide for concurrent transfer of information to and from input/output equipment. This is particularly effective since many input/output devices are electromechanical in nature and operate at speeds several orders of magnitude slower than the CPU speed. One technique used in small computers is to utilize *cycle-stealing* or *direct memory access (DMA)* between the input/output device and main storage. In this approach, the CPU provides the channel equipment with a starting storage address of the data to be transferred (or, in the case of an input device, the starting location of an input storage area) and the number of data words to be transferred. The channel equipment then independently transfers the information, using ("stealing") storage cycles not used by the CPU, while the CPU executes subsequent program instructions. In larger machines, the channel may have significant functional capability that allows it to do more than merely sustain the information transfer. For example, it may perform error checking on the data or automatically *chain* to the next input/output request upon completion of the current transfer operation.

Data Representation

Binary Notation. Virtually all modern computers utilize the binary number system and binary coded alphanumeric representations for internal data manipulation. The binary number system utilizes 2 as the number base or radix, as compared to 10 used in the familiar decimal number system. Only two digits, 0 and 1, are needed in the binary system, as compared to the ten symbols used in the decimal system. As in the decimal system, the quantity represented by a digit depends on its position in the numeral. Thus, the units position has a value of 1; the next position, a value of 2, the next 4, and so forth. As a specific example, the binary number 11010 represents the quantity $(1 \times 2^4) + (1 \times 2^3) + (0 \times 2^2) + (1 \times 2^1)(0 \times 2^0)$ or 26 (decimal). The binary equivalents of the first 20 decimal integers are:

Decimal	Binary	Decimal	Binary
1	00001	11	01011
2	00010	12	01100
3	00011	13	01101
4	00100	14	01110
5	00101	15	01111
6	00110	16	10000
7	00111	17	10001
8	01000	18	10010
9	01001	19	10011
10	01010	20	10100

Any quantity can be represented in the binary number system, although it requires considerably more digits than decimal notation. Binary representation is used in computers primarily because only two symbols are required and it is easy and economical to build electronic circuits having two states, "on" and "off," corresponding to 1 and 0.

The symbols 0 and 1 are called *bits* (a contraction of the words *bi*nary digi*t*). In some usage, it is common to refer to the 1 as a bit and to the 0 as no bit, even though this is technically incorrect.

Numeric Data Types. Two numeric data types are provided for arithmetic operations on most computers. These are known as *integer* (or *fixed-point*) and *floating point*. Integer data type provides for the representation and manipulation of whole numbers; i.e., $\ldots, -3, -2, -1, 0, 1, 2, 3, \ldots$. Integer arithmetic can be used for dealing with fractions (e.g., $0.575 + 1.2$) by appropriate scaling of the numbers (i.e., multiplying by factors of 10 in the decimal system to align the decimal point). When utilizing integer arithmetic in this way, the computer programmer is responsible for the explicit scaling of the numbers and for keeping track of the radix point. The advantage of integer arithmetic is that it is faster than floating-point and requires fewer circuits to implement. Its disadvantage is that the range of numbers that can be represented in the typical computer word is quite limited. For example, an 8-bit byte can be used to represent only 0 to 256 (or -128 to $+127$) and a 32-bit word only represents 0 to 4,294,967,296.

The use of the floating-point data type provides for a greater range of values by representing the quantity as a quantity *and* a scaling factor, in a manner similar to the use of "scientific notation" such as 0.424×10^{12}. In the computer, the fractional part and the exponent representing the scaling factor are stored separately. For example, the numeral might be stored in a computer word in the form:

s	e	s	f

This is interpreted as $\pm 0.f \times 2^{\pm e}$ where s represents the sign ($\pm$), e is the binary exponent, and f is the binary fraction. In performing floating-point arithmetic, the computer manipulates the fraction and the exponent separately. Some small computers do not provide hardware for floating-point arithmetic, in which case the programmer is restricted to fixed-point or must rely on programmed subroutines to perform the necessary manipulation.

The precision of the floating point number is determined by the number of bits in the fraction, whereas the span or range is determined primarily by the number of bits in the exponent. Thus, a one byte fraction and a one byte exponent provides representation of quantities from -0.128×2^{128} to $+0.128 \times 2^{127}$.

The advantage of using floating point numbers is the range of values that can be accommodated and the fact that the placement of the radix point is handled by the hardware or software. The disadvantage is that floating-point operations are slower, since the exponent and fraction are manipulated separately.

Character Coding. In addition to numbers, computers must deal with information composed of alphabetic characters and special symbols (e.g., @, #, $, *) and, since the computer circuits are designed to manipulate only 0 and 1, these characters must be coded into a binary notation.

A number of different alphanumeric codes are used. One of the most common is ASCII (pronounced "as-key," and an acronym for American Standard Code for Information Interchange, which is defined by American National Standard X3.4-1977 and its international counterpart ISO 646-1973). This code provides for the representation of 128 alphabetic (upper

and lower case), numeric, special symbol, and control characters in a 7-bit byte. Typically, a one-bit parity check is added (see below) and the character is stored as an 8-bit byte in the computer. The following are sample ASCII codes:

Numerals	1	0110001
	2	0110010
	3	0110011
Alphabetic	A	1000001
	a	1100001
	K	1001011
	k	1101011
Special	#	0100011
	(	0101000
	=	0111101
	?	0111111
Control	End of Text (ETX)	0000011
	Bell (BEL)	0000111
	Acknowledge (ACK)	0000110
	Cancel (CAN)	0011000

It is important to note that these codes are indistinguishable from the codes illustrated earlier for numeric quantities. Their interpretation as characters is determined by the intent of the programmer who writes the program for their manipulation. It is possible, and allowable in some computers, for example, to numerically add *A* to 6. Since this usually does not make sense, however, programs usually are designed to detect such operations and, at a minimum, notify the programmer of the use of mixed data types.

Error Detection and Correction. Many codes are designed to assist in ensuring that an error has not occurred in transferring data from one location to another. Such an error might happen if an electrical noise pulse upset a circuit such that it was turned "off," thus converting a 1 into a 0. One of the simplest error-detecting codes, often used internally in computers, is the *parity check*. In this scheme, the value of one bit in the code is selected such that the number of 1s in the coded character is either even (even parity) or odd (odd parity). For example, in even parity, the seven-bit representation 0110101 of a character would be altered by adding a leading 0 to form 00110101, whereas 1010100 would be altered to 11010100 so as to provide an even number of 1 bits, in this case four. If a single bit change error occurs, the number of 1 bits is no longer even and, when tested by the checking circuit, the error would be detected. Note, however, that any even number of erroneous bit reversals is not detectable by a parity check.

More sophisticated error detection codes sometimes are used in portions of computers and in digital communications. These are capable of detecting multiple-bit errors and may be capable of determining the exact error so that it can be corrected automatically. Such codes require additional bits in the representation and, therefore, have a cost in terms of additional circuits and storage capacity.

The Computer Word and Byte. Although single bits of information sometimes are manipulated in a computer, it is common to handle a group of bits in parallel. Through common usage, an 8-bit group usually is the minimum number of bits manipulated in parallel. Although the usage is not technically correct, this 8-bit group usually is called a *byte*. Technically, a byte is any portion of a *word* (see below) and there is a growing tendency to utilize the more specific words octet (8-bit byte), sextet (6-bit byte), etc. to avoid confusion. The octet is a convenient size to represent a character set, since it allows for 256 distinct representations, a number sufficient for the numerals 0–9, upper- and lower-case alphabetic characters, a generous number of special symbols, control codes, and parity.

A computer *word* typically is one or more bytes (usually 8-bit bytes). The internal circuits in the computer usually are designed to transfer to operate on a word, although instructions to allow the individual manipulation of bytes commonly are provided. In addition, the word is the usual amount of information obtained on a single storage access.

Since there is a correlation between the number of bits in the computer word and the number of circuits required in a particular design, and, additionally, there is a correlation between the number of circuits and the classes of computer represented by the so-called micro-, mini-, and maxi-, or main-frame computer, microcomputers typically utilize a one- or two-byte word (8 or 16 bits), minicomputers usually use a two- or four-byte word (16 or 32 bits), and main-frames usually use four- to eight-byte words (32 to 64 bits). However, this is a time-dependent association since, for example, only a few years ago microprocessors used only 4-bit bytes and 32-bit (4-byte) microprocessors were designed in the early 1980s.

Most instructions are contained in one word. Also, arithmetic and logical operations usually are performed on one-word operands. As previously indicated, however, most computers provide instructions for the manipulation of single bytes. This is particularly useful when manipulating characters coded into bytes. Since the length of the word determines the precision of simple arithmetic operations, the number of bits in the word may not be sufficient for some applications. As a result, many computers provide double-precision arithmetic operations, which use two-word operands. These usually require additional computation time, since the implementation merely provides for handling the two words individually. In addition, some instructions are contained in more than one word. This often is caused by the need to include an operand or a physical address in the instruction itself and the number of bits available often is not sufficient to express all of the needed location addresses.

Instruction Representation. A key digital computer concept is that the instructions that control the computer are themselves stored in the computer storage as binary codes. The instruction code is stored in one or more words and is accessed by the control unit when needed. Depending on the particular operation, a variety of information may be contained in the instruction. For example, in an addition operation, the computer must be told where the addend and augend are located and what to do with the resulting sum. For this reason, the format of the stored instruction varies with the operation to be performed. In general, however, an instruction consists of an operation to be performed, one or more addresses indicating the location of the operands, and, possibly, other modifiers or data. Thus, an instruction might be stored in the following format:

OP	R1	R2	R3

where OP represents the Operation Code, and R1, R2, and R3 are three addresses indicating the sources and destinations of operands and results. Using this format, the operation "Add the contents of register 1 to the contents of Register 3 and store the result in Register 2" might be coded as:

0110	0001	0011	0010

Here the Operation Code for ADD is coded as 0110, the address of Register 1 is 0001, the address of Register 2 is 0011, and the address of Register 3 is 0010.

A typical computer is capable of performing several hundred different instructions of this type. Sequences of such instructions direct the detailed operation of the hardware on a step-by-step basis. Determining the exact sequence for the solution of a particular problem is part of the task of the programmer as discussed below.

Although a particular computer may have several hundred instructions, they can be grouped into several major categories:

1. *Arithmetic Instructions*. These include the arithmetic operations, such as addition, subtraction, multiplication, and division. There may be several different ADD instructions, for example, to provide for integer and floating-point data types or to allow addition of quantities stored in particular locations in the computer; separate ADD instructions might provide for addition of quantities located in registers or addition of quantities stored in main storage.
2. *Logical Instructions*. These provide for the logical operations such as AND, OR, and Exclusive OR. Logical operators may act on single bit positions or on whole words or bytes.
3. *Data Movement Instructions*. These provide for the movement of data between various part of the machine. They might include, for example, "Move the contents of storage location x into Register y;" "Replace the contents of Register r with the contents of Register s;" or "Move the contents of storage locations x through y to input/output port z."
4. *Control Instructions*. These provide for the control of the sequence of operations. For example, a typical instruction might be "Transfer control to the instruction located in storage location x " or "execute instruction y if the contents of register 1 is negative, otherwise execute the next sequential instruction."

Basic Hardware Operation

The diagram of Fig. 3 is used to illustrate the basic operation of the computer. Although greatly simplified, the diagram shows the data paths between the functional units found in a typical CPU and its associated main storage. The CPU Control Unit (CCU) consists of circuits which "decode" (interpret) the Operation Code and subsequently provide the timing and actuation signals to control the other functional units in the CPU.

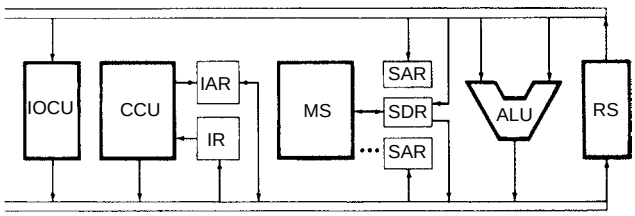

Fig. 3. Hypothetical computer data flow. CCU = central processing unit (CPU); MS = main storage; SAR = storage address register; SDR = storage data register; ALU = arithmetic logic unit; IOCU = I/O control unit; RS = register stack; IAR = instruction address register; IR = instruction register.

The Main Storage (MS) is used to store both the program (instructions) and the data on which it operates. Storage is organized as a sequence of locations, typically represented by a byte, which are assigned sequential addresses starting with 1. The amount of storage may vary from as little as a few thousand bytes in a small machine to millions of bytes in a large machine.

The Storage Address Register (SAR) holds the address of the storage location to be activated, either for the purpose of reading the contents of the location or for storing into the location.

The Storage Data Register (SDR) temporarily holds data being read into or out of storage.

The Arithmetic and Logic Unit (ALU) performs the specified arithmetic and logical operations on the data presented at its two inputs. The ALU output is routed to either the register stack, the I/O control unit, or main storage by signals from the CCU.

The Register Stack (RS) is a special-purpose storage unit, consisting of typically 16 to 64 locations that can be used for the temporary storage of data and addresses. It is used in lieu of main storage because it can be accessed much more quickly.

The I/O Control Unit (IOCU) represents the channel or other circuits which provide for the detailed control of input/output units such as video terminals, communication equipment, disk and diskette storage, and data acquisition equipment.

The Instruction Address Register (IAR) contains the location of the instruction currently being executed. It is normally incremented by 1 automatically to access the next sequential instruction.

The Instruction Register (IR) is a temporary storage location in which the current instruction is held during execution.

The basic operational sequence is as follows:

1. Fetch the next instruction from MS.
2. Fetch the operands (if any) from MS or RS.
3. Execute the operation.
4. Fetch the next instruction and repeat.

As a detailed example, consider the following sequence of instructions stored in sequential main storage locations (abbreviations are used to represent the operation codes, but the actual representation in storage is a sequence of binary codes as described earlier):

Storage Location	Instruction	Meaning
1	M,34,8	Move the contents of MS 34 into RS 8
2	M,87,6	Move the contents of MS 87 into RS 6
3	A,8,6,3	Add the contents of RS 8 to the contents of RS 6 and place result in RS 3
4	BCN,3,93,65	If the contents of RS 3 are negative, go to the instruction in MS 93; otherwise, go to the instruction in MS 65

The execution of this program fragment proceeds as follows: The address in the IAR is set to 1, indicating that the instruction in MS location 1 is to be executed. The CCU causes the contents of location 1 to be transferred into the IR where it is decoded by the CCU. The CCU transfers the data address (34) into the SAR and the contents of MS location 34 is transferred into the SDR and then routed to RS location 8. The operation is complete and the CCU increments the IAR by 1, causing it to advance to 2.

Since the IAR is set to 2, the instruction in storage location 2 is transferred into the IR and decoded. The sequence is the same as above except that the data in MS 87 is transferred into RS location 6. At the completion of the transfer, the IAR is incremented to 3.

The instruction from storage location 3 is placed in the IR and decoded. This causes the contents of RS 6 to be routed to one input of the ALU and the contents of RS 8 to be routed to the other input. The two numbers are added together by the ALU and signals from the CCU cause the sum to be stored in RS 3. The IAR is then incremented to 4.

The instruction in MS 4 is transferred to the IR and decoded. This causes the contents of RS 3 to be examined by the CCU to determine whether it is a positive or negative number. Assuming that it is found to be negative, the CCU replaces the contents of the IAR with 65, the address of the next instruction to be executed.

Control of the program has now been transferred to the instructions located at MS 65 and the basic fetch-execute-increment cycle continues. This example is simplified greatly but it is conceptually accurate. In an actual computer, many operations may take place during a single instruction execution. For example, the address of the data may not be explicitly contained in the instruction, so that the CCU may have to fetch data from storage and perform some calculations to determine the actual address of the data. Similarly, a single instruction to send data to a printer may involve a number of data transfers between main storage, registers, and the IOCU, all under control of the CCU.

In this brief entry, it is only possible to present basic concepts and definitions associated with digital computer hardware. Although similar in concept, there are many variations in the hardware design of a computer. Many of the details of these variations and the interconnection of the internal functional elements of the CPU are included as separate entries in this encyclopedia. The reader is referred to these entries or to the references listed at the end of this entry for more comprehensive treatment of specific concepts or hardware elements.

Computer Programming

The computer hardware is controlled by a sequence of instructions, which are stored in main storage. The sequence of instructions is called a *computer program* and the act of devising the particular sequence needed to solve a given problem is called *computer programming*. Collectively, the set of programs and associated documentation available for a particular computer is referred to as *software*.

Programming consists of all those activities associated with the production of the actual program. This includes determining the solution to a problem, describing or organizing the solution in such a way that the computer can be used efficiently, coding the solution in a form acceptable to the computer through the use of a programming language, testing the resulting program, and maintaining the program and its documentation over its useful life.

The first phase, problem definition, involves a thorough understanding and description of what the computer is expected to do. This includes understanding what data are available, what errors are likely to be encountered (e.g., a person's name containing a numeral), what data manipulation is necessary, and what results are expected. It is also necessary to understand the characteristics of the data, such as whether certain parameters are positive or negative, the range of numerical inputs, the desired numerical precision, the number of data items to be handled or stored, and the desired format for the results.

Once the problem is defined, a procedure must be devised which provides the desired solution. This typically is done by breaking the problem into a set of subproblems, each of which can be addressed separately. For example, in a payroll calculation, the subproblems might include:

1. Calculating hours worked from starting and ending times.
2. Determining gross wages, including overtime and shift premiums.
3. Calculating income and social security withholding tax.

4. Calculating automatic deductions (e.g., savings bonds or insurance) and arranging for crediting them to the proper account.
5. Calculation of net pay and year-to-date values.

Very often, this decomposition of the problem is facilitated by graphical or other techniques that are useful in organizing the solution. In one popular technique, called *flowcharting*, each subproblem is represented by a block with the relation between blocks illustrated by connecting lines. Blocks having different functions (e.g., input, output, decisions, calculations, etc.) often have distinctive shapes. American National Standard X3.5-1970 describes a set of such symbols and their use. Following the overall decomposition of the problem into subproblems, each of the major steps (blocks in the flowchart) is further decomposed into a more detailed flowchart.

Once the solution is planned, it must be translated into a sequence of computer instructions that represent the program. Although the actual program representation in storage is a series of bits, attempting to write a program in this representation is difficult and error prone, due to the need to manipulate the inconvenient binary codes. As a result, programming languages have been devised to ease the task and reduce the chance for error.

There are many programming languages available for most computers. In general, however, they can be categorized as assembler languages, macroassembler languages, higher-level or procedural languages, and problem-oriented languages. In assembler language, the binary code for each operation code is represented by a mnemonic code. For example, the binary code 01101 meaning ADD REGISTER might be represented by ADR. Similarly, address locations are represented by mnemonics chosen by the programmer; for example, NP may represent Net Pay. The program is coded using these symbols and might appear as follows:

```
ADR, 1, NP
M, 34, 86
CMP, 3, RES
```

The resultant program, called the *source program*, is used as data for an assembler program which substitutes binary codes for the mnemonic codes and assigns a physical storage address in place of the mnemonic address. The assembler program output is a sequence of binary words (bytes) which can be placed in storage for execution. This binary-coded program is called the *object program*.

It is soon discovered when using assembler language that there are particular sequences of operations that are used frequently. For example, reading a character from a keyboard may require the same 100 assembler language instructions for each character read. Rather than writing this sequence each time it is needed, the whole sequence can be assigned a name such as KEYI, standing for Key Input. Whenever the programmer needs to read a keyboard input, the mnemonic KEYI is inserted in the assembler language program. The sequence of instructions KEYI is called a *macro*. When the program is processed using a macroassembler to produce the object program, the computer inserts the entire instruction sequence represented by KEYI whenever it appears. This technique can reduce significantly the effort needed to code a program.

Procedural languages go a step further and provide even greater function for each statement in the source program. For example, a typical procedural language allows the programmer to write

$$A = B + C/D \times E$$

in order to express a mathematical calculation. Similarly, control statements can be expressed in a form such as:

$$\text{IF} \times \text{GT y THEN z} = x - y \text{ ELSE z} = y - x$$

These statements are not executable directly by the computer and must be translated into a sequence of binary-coded instructions. This is done by a program called a *compiler*, or an *interpreter*, which analyzes each statement and substitutes the necessary sequence of instructions to accomplish the desired result. Each statement in the procedural language source program creates many machine instructions. As a result, the productivity of the programmer is greatly enhanced. A number of high-level procedural languages are in common use. These include, for example, FORTRAN, COBOL, Pascal, LISP, and BASIC. A majority of programming today is done using such languages to express the problem solution.

Problem-oriented languages are similar to procedural languages except that they are designed for the solution of a specific class of problems. They often use a vocabulary that is unique to a particular field. For example, a typical statement in a problem-oriented language for process control applications might be:

```
AT 1500 HRS CLOSE VALVE V1 WAIT 10 SEC TEST
```

A source program written in such a language must also be processed by a compiler or interpreter program before it can be executed by the computer.

Once the solution to the problem has been described in a programming language and processed by an assembler, compiler, or interpreter program, it must be tested for correctness before being used. Errors in programs are called "bugs" and the process of finding and correcting them is referred to as "debugging." A variety of techniques are utilized in this process. Most assemblers, compilers, and interpreters include facilities which identify errors associated with the syntax and semantics of the programming language being used and other detectable errors such as an expression involving mixed data types (e.g., attempting to add a character to a number). Errors in the problem solution, of course, cannot be detected by these language processing programs. These are usually detected by visual inspection, sometimes by a second programmer who was not involved in the original writing of the program, and by using test data to determine if the results are as expected. Many errors are associated with the interaction of a particular program with other programs being used concurrently. These are detected when the program is integrated into the total set of programs being used on the computer.

Debugging a program is a difficult task since all possible combinations of data must be considered. It is usually impossible to exhaustively test a program, so it is likely that some bugs will remain undetected until the program has been in use for some time. It is this phenomenon which gives rise to the need for maintenance over the life of the program.

System Programs

Programs can be separated into the two major categories of *application programs* and *system programs*. Application programs are those programs directly involved in the solution of a user's problem and are typically related to the business of scientific purpose of the program. Thus, for example, accounting programs, data base inquiry programs, and airline reservation programs are application programs.

Considerable programming, however, is required just to control the internal operation of the computer, independent of the particular application. The suite of programs used for this purpose often are called "system programs." In general, these provide facilities and services that are useful to the application programmer and serve to free the programmer to concentrate on the details of the application. A major example of this is the so-called "operating system," "monitor," or "executive" program which handles many of the internal details associated with running an application program.

In present computers, it is common for several application programs to be in main storage simultaneously and be executed concurrently. Two terms associated with this type of operation are "time-sharing" and "multiprogramming." In time sharing, each program is executed for a fixed period of time or until the program needs a computer facility that currently is not available. At that time, the program is halted temporarily and another program is executed. After every active program has an opportunity to execute, the computer returns to the original program. Because of the speed of the computer, the individual user often is not aware that their program has been interrupted several times during its execution.

Multiprogramming is a generalization of time-sharing, where the computer facilities are shared among several programs based on the availability of resources, such as input/output devices, or some other criteria. For example, a priority scheme may be used where more important programs are allowed precedence over other programs. Less important programs are not allowed to run until higher-priority tasks are completed.

The scheduling of the programs in a time-sharing or multiprogramming environment is one of the important functions of the operating system. In addition, the operating system often provides detailed control of input/output devices, such as disk files and printers, and security features that, for example, ensure that a program does not access data for which it is not authorized. The computer typically spends more time executing operating system code than it does application programs. As a result, the design of the operating system is crucial to the performance perceived by the user.

In addition to the operating system, a suite of programs referred to as "utility programs" usually are provided. These include the assemblers, compilers, and interpreters needed to process the high-level language source programs. Other utilities are housekeeping programs for rearranging storage, for testing the correct operation of the computer and its peripheral devices, and accounting programs to aid in billing users for their portion of the computer time.

MODERN AND FUTURE DIGITAL COMPUTERS

(Late 1980s to the Year 2000+)

For a number of years, physicists, mathematicians, and computer scientists have shown much interest in what physical factors of nature will ultimately establish the upper limits of computer performance — capacity, speed, accuracy, reliability, flexibility, and, indirectly, cost, among other factors. Such interests date at least as far back as the 1940s when Claude E. Shannon of the Bell Telephone Laboratories (now AT&T Bell Laboratories) established a theory of communication and, in essence, the beginnings of modern information science. See article on **Information Theory**. As semiconductor processing progressed to smaller and smaller discrete dimensions, authorities began to wonder about the ultimate limits of the technology and how these limits (information density, etc.) may establish ultimate limits in computer design. But, as pointed out in the article in this encyclopedia on **Molecular and Supermolecular Electronics**, present device concepts now widely used in digital computers may become obsolete sometime after the year 2000.

For the relatively near-term period, better computer performance appears to be developing from changes in computer architecture rather than what might be termed *radical* changes in components. It is generally accepted that advanced computer architectures and, in particular, vector processing and multiprocessing architectures will provide the potential for much higher computational speeds, as well as access to large central memories, than has been the experience of the computers of the last few decades. Today, the best known and most widely used advanced architecture machines are the so-called supercomputers, as typified by machines such as the Cray-1, the CDC Cyber 205, the Cray X-MP, the Cray-2, and the Cray Y-MP8/864. This last is used in advanced climatological studies as, for example, the prediction of weather in space as reflected by the thermosphere-ionospheric general circulation model (TIGCM) being carried out by the National Center for Atmospheric Research (NACR) in Boulder, Colorado. See also **Climate**.

Advanced Computer Architectures[7]

Earlier in this article, the von Neumann model was briefly described. See also Fig. 4. Sequential fetch/execute cycles in a von Neuman processor result in slow operation. An instruction must be fetched from memory and decoded; then an operand must be fetched, followed by instruction execution. Programs implemented are performed in a step-by-step sequence of fetch/execute cycles. For digital signal processing (DSP), this can be a relatively slow process since each memory fetch can take 50 nanoseconds or more. A variation of the von Neumann scheme (Fig. 5), the Harvard architecture, speeds computations by feeding data and instructions simultaneously into a processing unit.

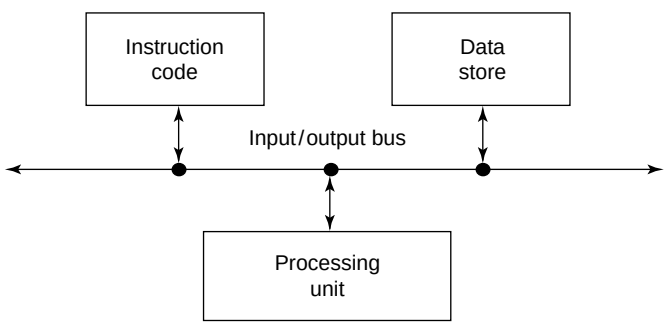

Fig. 4. Sequential fetch/execute cycles in a von Neumann processor result in slow operation. An instruction must be fetched from memory and decoded; then an operand must be fetched, followed by instruction execution. Programs implemented are performed in a step-by-step sequence of fetch/execute cycles. For digital signal processing (DSP), this can be a relatively slow process since each memory fetch can take 50 nanoseconds or more.

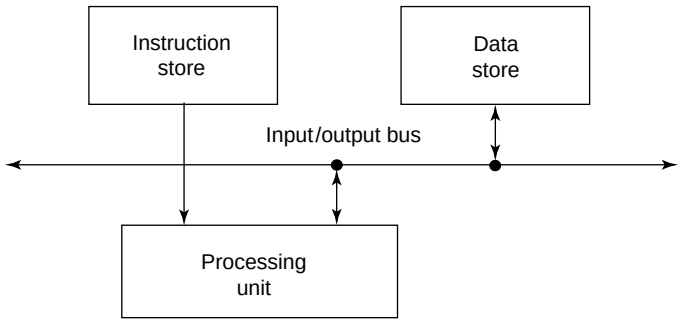

Fig. 5. A variation of the von Neumann scheme. Harvard architecture speeds computations by feeding data and instructions simultaneously into a processing unit.

Parallelism. A key element in advanced computer architecture is *parallelism*. There are several ways in which a computer can be made to operate in parallel. Flynn (see reference) proposed four categories of parallel designs:

1. Single-instruction single-data-stream (SISD).
2. Single-instruction multiple-data-stream (SIMD).
3. Multiple-instruction single-data-stream (MISD).
4. Multiple-instruction multiple-data-stream (MIMD).

In the SISD (which includes most contemporary computers), only one instruction is executed at a time, and the instruction operates on only one data stream. In an SIMD computer, there is an array of separate processors, each capable of doing the same instruction at the same time on a different data stream. For example, a single instruction could compute the sum of two vectors. Assuming enough processors were available, all the additions of the corresponding elements of the operand vectors could be done simultaneously. In this case, the processing is synchronous, i.e., all processors must begin to execute the instruction at the same time. It should also be noted that various schemes can be used to interconnect the processors, and to connect them to memory.

In an MIMD computer, there is again an array of separate processors, and again the processors may be connected to each other and to memory in a variety of ways. In this case, however, each processor is capable of doing *different* operations on different data streams. Also, in an MIMD machine, processing is usually asynchronous, i.e., the different processors may start their different operations at different times.

Finally, in the MISD machine, a single data stream is operated on by a sequence of different processors, each capable of different instructions. This last category is considered by some as not very useful because it is regarded as impractical and there are no real implementations.

A second, and more serious, problem with this classification scheme is that there is no good agreement on where to categorize "pipelined" machines. They have been categorized by various authors as SISD, SIMD, and MISD. For these reasons, it is perhaps better and simpler to classify advanced computer architectures into three categories: (1) vector processing; (2) multiprocessing; and (3) vector multiprocessing.

Vector Processing. This category includes SIMD machines as well as "pipelined" computers, because both facilitate the processing of identical operations on large vectors or arrays of numbers. Pipelining is perhaps best explained by using an assembly-line analogy. For example, a floating-point operation involves several steps. Without pipelining, all the steps needed to complete an operation could be performed before starting the first step of the next operation. Thus, in effect, the computer works on one operation at a time. In contrast, to perform a particular operation in a highly pipelined computer, there are several "stations" each of which performs only one step of the overall operation. Since, as in an assembly line, all stations are working concurrently, the computer can perform each step of the operation on different data at the same time. Examples of this type of computer are the Cyber 205 and the Cray-1. Both are highly pipelined machines, although they operate somewhat differently. For instance, the Cyber 205 operates most efficiently on very long vectors, while the Cray-1

can operate efficiently even on relatively short vectors. Rudimentary forms of pipelining can also be found in some conventional machines.

As mentioned, SIMD computers are composed of an array of separate processors, each performing the same operation at the same time, but on different data. Perhaps the best known high-performance machines of this type are the ILLIAC IV, now retired, and the Massively Parallel Processor (MPP) built for NASA by Goodyear Aerospace, primarily for image processing. The ILLIAC IV, which had an array of 64 processors, could, for instance, add two 64-element vectors in about the same time as a scalar addition, since all 64 scalar additions needed to add the vectors could be done in parallel.

Multiprocessing. This category covers MIMD architectures that use an array of *scalar* processors, each capable of executing different instructions at the same time on different data. The term "parallel processing" is generally regarded as synonymous with multiprocessing. It should be recognized, however, that "parallel processing" is a term whose meaning has evolved over a number of years, and which may be misleading in some circumstances. Two examples of commercial multiprocessors are the BBN Butterfly and the Intel iPSC. There are also a number of experimental prototype machines of this type, as well as other machines in various stages of commercialization. Some conventional machines can also be thought of as "loosely coupled" multiprocessors.

The vector multiprocessing category ("parallel vector processing") is essentially a combination of vector processing and multiprocessing. There are several processors that can run in parallel, and each of these processors is itself a powerful *vector* processor, generally of the pipelined type. Most state-of-the-art supercomputers, such as the Cray X-MP and the Cray-2 fall into this category, and plans for newer machines suggest that this architecture will continued to dominate the high end of the supercomputer market for at least the short-to-medium term. Currently available state-of-the-art machines have up to eight vector processors in parallel, a number that is expected to grow significantly over the next few years.

Architectural Details

In the machines mentioned, the extent to which their computing capability can be exploited largely depends on how well the software is tailored to that type of architecture. In a factor processor, for example, this would depend on the extent to which a problem, code, or algorithm can be "vectorized," i.e., put into a form in which as many operations as possible are done on vectors. Because the architectures of these machines vary greatly from each other, it is necessary to know more about the architecture of the computer in order to write efficient software for a particular machine. Some important considerations for advanced computer architectures are discussed in the next few sections of this article.

Processors. The individual processors used in advanced architectures range from inexpensive, relatively slow microprocessors, such as the 90286 processors in the Intel iPSC to the extremely fast, custom-designed processors, such as those used in the Cray-2. The early supercomputers (e.g., Cray-1) were generally composed of one very fast pipelined processor. The most recent generation of supercomputers (e.g., Cray-2) includes machines with several very fast processors. Early prototype multiprocessors, however, were generally composed of microprocessors because of cost, availability, and reliability. Recently, commercial machines composed of microprocessors have begun to appear. It has been discovered that, in many applications, by using many slower and inexpensive microprocessors, one can reach the same computational speed as with one fast processor, and that this often results in lower cost. The microprocessors currently used most often are the 8026/80286 and the 68000 so, in a sense, these computers can be thought of as arrays of PCs.

While the processors in these multiprocessing machines are microprocessors that operate sequentially themselves, many of the custom-made and all of the fastest supercomputer processors include other levels of parallelism within their processors. For example, the Cray-2 computer currently has up to four processors. There are multiple pipelines within each of these processors, so not only can more than one processor be working on a program, but also more than one pipeline within each processor can be working simultaneously.

Memory Access. Mutliprocessors also differ greatly in the way they access memory. In some computers, each processor has its own local memory. If a processor needs data from another processor, the data must be passed from the memory of one processor to the memory of the other processor. At the other extreme, some computers have a *global memory*, i.e., all of the processors access the same memory. In this case, it is unnecessary to transfer data between processors. Normally, the memory is divided in such a way that only one processor can access a particular portion of memory at a time. Because of potential conflicts between different processors attempting to access the same memory bank at the same time, relatively few processors have been used in machines with such a shared memory.

Other machines have memories that lie somewhere between local and global. For example, a computer can have a number of separate memories that can be dynamically assigned to the different processors through some sort of interconnection network as a program is executing. The memory is global in the sense that it can be accessed directly, although not simultaneously, by all processors, but it is not truly global since it comprises a set of separate memories.

Some computers have more than one level of memory. Often there will be a relatively small fast memory, used to keep only those variables and portions of code that are currently needed, and one or more levels of slower memory. Other multiprocessors have both local and global memories. The presence of the global memory allows data to be shared without requiring data transfers between local memories that could be very time consuming or that could tie up the processors. The local memory can be accessed more quickly than global memory.

Interconnection Schemes. The interconnections between the individual processors in a multiprocessing computer also vary a great deal. Connections can be classified as either (1) static, or (2) dynamic. Static schemes have fixed connections between processors; dynamic schemes allow for switching of interconnections while a program is executing.

In the ideal *static scheme*, each processor would be connected to all other processors in order to facilitate the transfer of data from one processor to another. The number of connections needed for this is $N\ (N-1)/2$, where N is the number of processors. This number is not very large for small N. However, 16 processors would require 120 interconnections; 64 processors would require 2016 connections; 256 processors would require 32,640 interconnections. In practice, these large numbers of connections are not feasible because of insufficient space within the computer. Because of this, other interconnection schemes have been devised that attempt to allow for efficient transfer of data between processors, but with fewer interconnections between the processors.

Nearest-Neighbor Mesh. One interconnection scheme that was initially popular is the nearest-neighbor mesh (Fig. 6). This is a two-dimensional rectangular grid where each processor is connected to the four nearest processors. Two-dimensional finite-difference grid problems often adapt nicely to this sort of architecture since solutions at one grid point normally depend on the values at the nearest neighbors-exactly those processors which are directly connected.

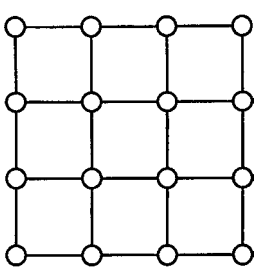

Fig. 6. Nearest-neighbor interconnection scheme.

Tree Architecture. Another architecture that has attracted some interest is the tree architecture (Fig. 7). This type of architecture appears to lend itself nicely to the decomposition of problems, i.e., a root node processor could distribute part of a problem to each of its branch node processors. These processors could, in turn, decompose the problem further and these parts could be processed by the next level in the tree, and so on.

Other Interconnections. There are several other interconnection schemes that have been proposed, including the *linear array* (Fig. 8), *ring* (Fig. 9), *star* (Fig. 10), and variations of these. Perhaps the architecture receiving the most interest currently is the *hypercube*, or *N-cube*. The

Fig. 12. Bus interconnection scheme.

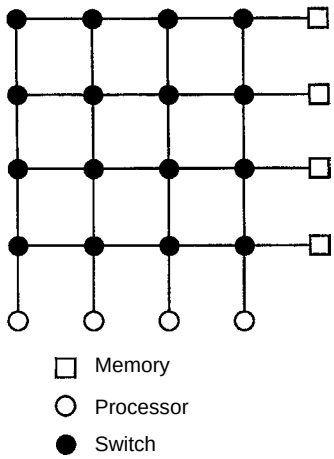

Fig. 13. Crossbar interconnection scheme.

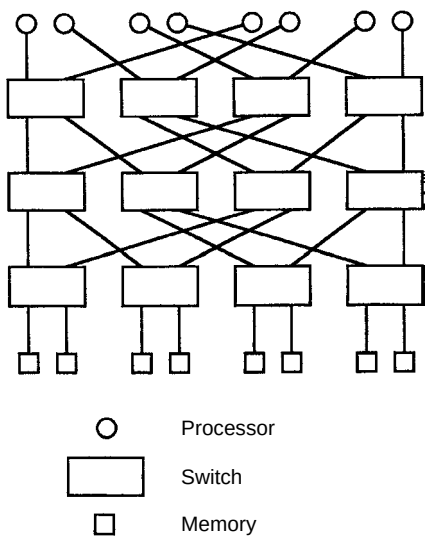

Fig. 14. Omega interconnection network.

hypercube scheme connects 2^N processors so that each can communicate directly with N other processors. The three-dimensional case is shown in Fig. 11. One reason for the popularity of this scheme is that many other interconnection schemes, such as the ring or linear array, can be considered as a subset of a hypercube. For example, if an algorithm is designed to work well with a ring-connected array, it will often work well on a hypercube.

One dynamic scheme of connecting the processors is to connect them to a single pathway, a *bus* (Fig. 12). All transfers of data must occur over this pathway. Unfortunately, the bus can only be used to pass one datum at a time. Hence, this connection scheme is suitable only for a very small number of processors, where there would not be a lot of contention for this single pathway.

It is not necessary that dynamic interconnections be between processors. Interconnections between processors and separate memories, like those previously mentioned, are sometimes used instead. One such scheme is the *crossbar switch* (Fig. 13) which essentially connects all processors to all memories. This switch allows every processor to be connected to a different memory simultaneously. Other switching networks have been used as well, such as the banyan network, omega network, and the Batcher network. See Fig. 14.

Other Issues in Advanced Computer Architecture

Nearly all of the contemporary computers with advanced architecture today run a high level language, usually Fortran. Special instructions are often added to both high and low level languages to better take advantage of the architecture. Of course, vector computers have vector instructions to perform in one instruction what would normally be a series of instructions in the form of a DO loop on a sequential computer. Other statements are often added. For example, the Cray computers have a vectorizing compiler that attempts to vectorize as much of the code as possible. The compiler is prevented from vectorizing if loops contain data dependencies, however. For example, in the following code the compiler would assume that the elements of the array computed in the second line depend on values of elements computed within the DO loop, even though no such data dependency actually exists.

```
      DO 10I = 1, N
      A(I + N) = A(I) + B(I)
10    CONTINUE
```

Thus, the loop would normally not vectorize for this reason. A special compiler directive is provided, though, that forces vectorization to occur despite an apparent data dependency in the loop. For example, the loop:

```
CDIR$   IVDEP
        DO 10 I = 1,N
        A(I + N) = A(I) + B(I)
10      CONTINUE
```

would vectorize because the additional statement instructs the compiler to ignore the assumed data dependency.

In multiprocessors, additional instructions are needed to allow parts of programs to be synchronized or to allow a precedence order between parts of code. For example, the Cray X-MP has a library routine (EVWAIT) that causes execution of code to wait until another routine (EVPOST) is called. Also, routines exist on some other multiprocessors to allow for the transfer of data from one processor to another.

Performance of Advanced Computers

The traditional way of measuring the performance of a computer has been expressed in how many MIPS (millions of instructions per second) it can perform. Parallel computers have rendered this measure rather meaningless because one single instruction can perform many operations, tens of thousands in some cases. A more meaningful measure of a computer's speed is how many MFLOPS (millions of floating point operations per second) it can perform. Unfortunately, this measure also can be misleading because the number of MFLOPS a computer actually performs depends greatly on how well the code is written to take advantage of the architecture of that particular computer. It is not unheard of for MFLOPS rates to vary well over an order of magnitude for different programs. Manufacturers often list a MFLOPS rating of their computers. Often this is a peak rate and computation cannot be sustained at this rate for a long period of time. By comparing the MFLOPS rate for a particular code with the peak or peak sustainable MFLOPS rate, however, one can get a good idea of how well a particular code takes advantage of the computer's architecture.

Another factor used to measure the performance of an algorithm or program in this regard is "speedup." On a multiprocessor, speedup is defined as the time it takes to complete a job using only one processor, divided by the time the job requires using P processors. Ideally speedup would be P, indicating that the algorithm could be performed in P independent parts of equal size. Often, the speedup is divided by the number of processors and is then called the efficiency.

It has been shown, based on a very simple model of parallel processing, that if the fraction of code that can be performed in parallel on P processors is f, then the maximum speedup S is $P/(P - fP + f)$, a relationship known as Amdahl's law. See plot of Fig. 15. (Amdahl reference.) Speedup is a measure that can also be used with vector computers. In this case it is the ratio of the time it takes for a job to execute without vectorization to the time it takes for a job to execute with vectorization. For vector computers, one can obtain an equation identical to Amdahl's law. In this case, however, f refers to the fraction of the code that vectorizes, and P refers to the ratio of peak vector speed to peak scalar speed. It can be seen from Amdahl's law that significant speedup requires that substantial portions of the code be run in parallel. Note, for instance, that with 64 processors, just 5% non-parallelized code will result in a maximum speedup of 15.42 (or a maximum efficiency of only 24%). Even very small amounts of non-parallelized or non-vectorized code can cause very significant losses in overall efficiency. In fact for f less than about 80%, the value of P tends to make relatively little difference in the overall speedup S. Unfortunately, many large general-purpose scientific codes, NASTRAN for example, do not vectorize more than about 50–60%, nor do they parallelize significantly better.

As noted by Levesque (see reference), Amdahl's law can be observed in the marketplace. If one looks at a pair of supercomputers from Fujitsu, the VP-100 and VP-400, one can observe that even though the VP-400 is four times faster in vector mode than the VP-100, many application programs do not vectorize sufficiently to utilize this speed. Thus, the slower, less expensive VP-100 has been commercially the most successful. Similarly, Levesque has compared the computational and marketplace performance of three supercomputers from the mid-1970s. The base case for this comparison is the CDC 7600, which was regarded as the fastest conventional mainframe in the mid 1970s. The three supercomputers compared are the ILLIAC IV and STAR 100, both early supercomputers, slower than the 7600 by a factor of four in scalar mode, but with vector speeds 16–20 times faster than the 7600, and the Cray-1, introduced in the mid-1970s, with a scalar speed twice that of the 7600, but a vector speed only 10 times as fast as the 7600. Using Amdahl's law, it is easy to show that, because of their slow scalar speeds, the ILLIAC IV and STAR 100 will not outperform the CDC 7600 until the percent vectorization reaches about 77%. On the other hand, because of its higher scalar speed, the Cray-1 will always outperform the 7600, and will outperform the ILLIAC IV and STAR 100 at percentages of vectorization less than about 98%. Based on Amdahl's law, it is not surprising that the ILLIAC IV and STAR 100 were commercially unsuccessful, while the Cray-1 was. The Cray-1 was successful in this marketplace because it offered both higher scalar speed and vector processing, even though its vector speed was not the best available.

These arguments can be extended to present multiprocessing architectures. In Fig. 16, Amdahl's law is replotted to show the speedup versus the number of processors for several values of the percent parallelization f. Note that, for a parallelization of 60%, Amdahl's law shows that there is little to be gained in overall speedup by having more than about 6–8 processors. Even for 80% parallelization, which is rare in most scientific computing today, there is little to be gained by having more than about 30–35 processors. This suggests that *large* arrays of parallel processors may not be useful as a *general-purpose* computing resource. However, as emphasized by Levesque, the situation regarding parallel processors on a large number of processors is not as bad as it might seem. For instance, today there are some applications for which very high levels of parallelization (approaching 100%) are possible. Among these are signal processing, image processing, and some finite difference codes. Furthermore, in the future we can expect numerical algorithms and codes that take much better advantage of parallelism than today. In part, this may be done using programming languages with built-in parallelism, so that compilers can

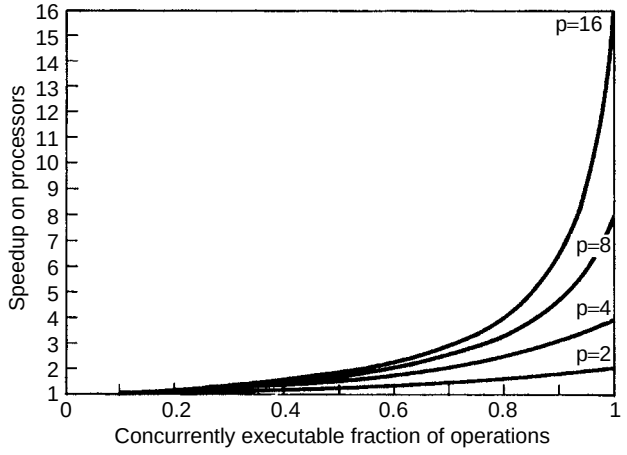

Fig. 15. A plot of Amdahl's law: S vs. f for several values of P.

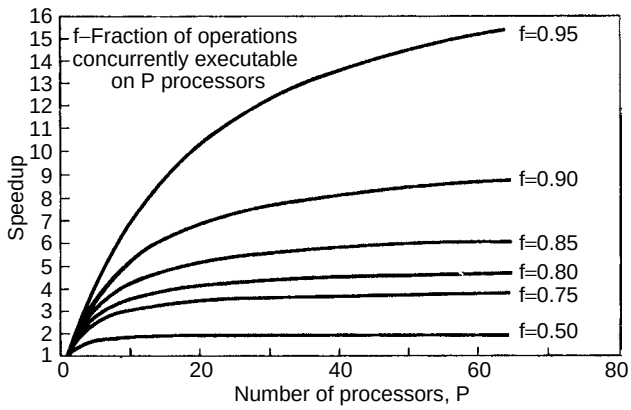

Fig. 16. A plot of Amdahl's law: S vs. P for several values of f.

optimize object code to best utilize parallel processing. Today's Fortran is difficult for compilers to optimize for parallelism.

Fuzzy Logic

As previously described, digital computers do not *reason* like the human brain, but rather they manipulate precise facts that have been reduced to a succession of zeros and ones and by statements that are true or false. In contrast, the brain handily processes information of an approximate and uncertain nature. The brain does very well in dealing with partial truths or falsifications. In *fuzzy* computer logic, solutions can be sought to less precisely stated (fuzzy) information and to assumptions, which, in a way, can be likened to iteration that may be derived from experience, or by seek-and-try methodology. Fuzzy logic is a technique that has been experienced over several years of usage in the industrial process control field. See also **Adaptive Control**; and **Artificial Intelligence**.

Fuzzy logic systems extend beyond process control and may be used to model any continuous system. Aristotle recognized the "middle ground" in the 300s B.C. He proposed the "law of the middle" — it is not hot, or cold, but "just right." In standard set theory, a quantity fits or does not fit. No allowance is made for in-between values. Fuzzy sets can deal with fuzzy boundaries.

In an excellent paper on this topic, B. Kosko (University of Southern California, Irvine) and S. Isaka (Omron Advanced Systems) summarize the current status of fuzzy logic very well: "... like any other mathematical or computer model, fuzzy logic falls prey to the 'curse of dimensionality' — the number of fuzzy rules tends to grow exponentially as the number of system variables increases. Fuzzy systems must contend with a trade-off. Large rule patches mean the system is more manageable but also less precise. Even with that trade-off, fuzzy logic can often better model the vagueness of the world than can the black-and-white concepts of set theory. For that reason, fuzzy logic systems may well find their way into an ever growing number of computers, home appliances and theoretical models. The next century may be fuzzier than we think."

Neural Nets

With some resemblance to fuzzy logic, a neural network learns from experience. Neural nets can handle problems involving data that are imprecise and "noisy" as well as those that are highly nonlinear and complex. Neural nets mimic the human learning process. Neural nets can identify and learn correlative patterns between sets of input data and corresponding target values. Once trained, such nets can be used to forecast outcomes from new input data. Such nets are well suited for pattern recognition, and they do not require a prior fundamental understanding of the process or phenomenon being modeled.

As pointed out by P. Bhagat (Exxon Research and Engineering Co.), "Neural nets operate analogously. A net must be trained by being repeatedly fed input data together with corresponding target outcomes. After a sufficient number of training iterations, the net learns to recognize patterns in the data and, in effect, creates an internal model of the process governing the data. The net can then use this internal model to make predictions for new input conditions." The process is analogous to a child when learning to recognize shapes. A personal computer is adequate for many neural net applications, but neural nets also are run on supercomputers. See Figs. 16, 17, and 18.

The neural net has been particular helpful to solving problems in chemistry and chemical engineering. In this area, several neural net "shelf" software programs have been used successfully. Complex heating/cooling and reacting processes are typical. Other applications have included the design of laboratory and pilot-plant experiments.

Banks also have used neural networks to evaluate mortgage-loan risks. As reported by H. Brody (Massachusetts Institute of Technology), "Over time, as it (neural network) processes more applications and tracks the outcome of the loan, the network will refine its model. It will adapt internally as market conditions change. In this the system differs fundamentally from an expert system, which relies on a static set of rules."

The Collaboratory Concept

Just a few years ago, W.A. Wulf (University of Virginia) defined *collaboratory* (collaboration/laboratory) as "a center without walls at which numerous researchers of multidisciplines and at numerous locations can perform their research without regard to physical location — interconnecting with colleagues, accessing instrumentation, sharing data and computational resources, and accessing information in digital libraries." Wulf additionally observed, "The essence of the collaboratory is not the physical information, but rather it is the software that enables scholars to use remote libraries, collaborate with remote colleagues, interact with remote instruments, analyze data and test models — all with nearly the facility they now enjoy locally." (See Wulf reference listed.)

In 1993, the National Research Council (NRC) issued a report, "National Collaboration: Applying Information Technology for Scientific Research." (See reference listed.) The report highlighted the following points:

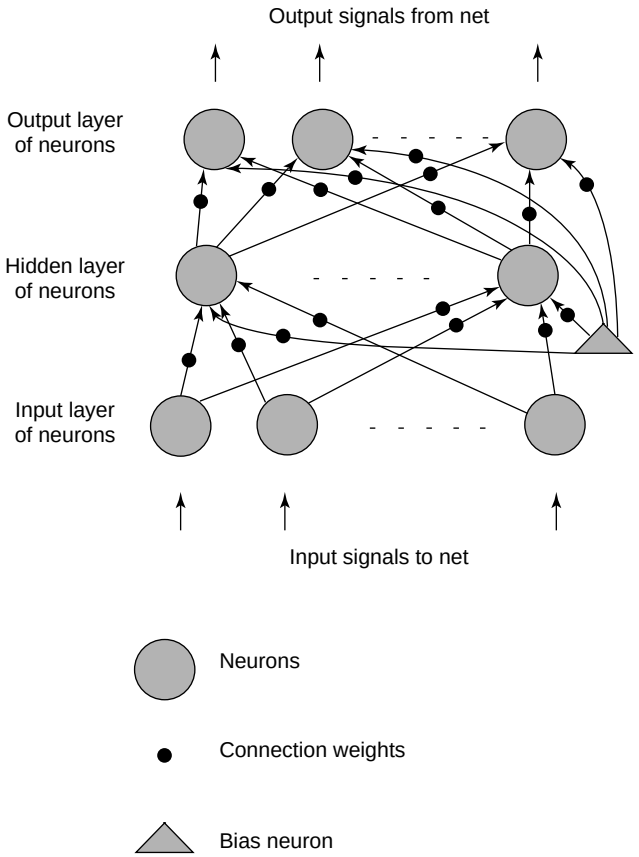

Fig. 17. Schematic diagram of a representative neural net. The system is made up of interconnected simulated *neurons*. The neuron may be described as an entity that is capable of receiving and sending signals as may be simulated by software algorithms on a computer. Each simulated neuron receives signals from other neurons, sums these signals, and transforms this sum by means of a sigmoidal function. The neuron sends the results to other neurons. Weighting modifies the signal being communicated This weighting is associated with each of the connections between neurons. The "information content" of the net is contained in the set of all of these weights. These, together with the net structure, make up the model generated by the net. The structure is believed to be a gross simplification of the general manner in which the human brain processes information, thus the term *neural*. (*After Bhagat, Exxon Research and Engineering Co.*)

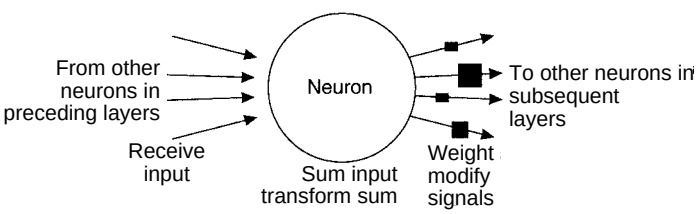

Fig. 18. Function of a neuron in a neural net. The net is "trained" by adjusting weights to minimize errors. P. Bhagat, in connection with a stirred reactor problem, designed a neural net computer simulation that utilized 15 input neurons, seven hidden neurons, and one output neuron. A mathematical model for two reactors in series generated the data for training and testing the network, but actual plant data also could have been used. (*After Bhagat, Exxon Research and Engineering Co.*)

1. *Scientific Database*. Huge databases are being created. Examples: Global Seismic Data; Genome Project; Space-Based Measurements of Earth ("Mission to Earth," etc.). These databases differ markedly from business-oriented data depositories. Scientific databases may not be text, nor may they be numeric. They may not be instantaneous in nature, but may reflect very long-term trends. Some of the data may represent phenomena "yet to be discovered." Thus, the stark contrast with the crisp, definitive information of an automated bank teller, for example. Computer design to date has largely reflected the latter kinds of needs.

2. *Remote Instrumentation*. In many scientific research settings, the data-sensing function does not occur in an immediate laboratory facility, but rather in very remote areas, as typified by instruments aboard spacecraft, or in connection with deep sea oceanographic experiments. Borrowing from the "smart" or "intelligent" sensor concepts, developed a decade ago for industrial process control applications, remote sensors not only must deal with their immediate environment, but also should be imbued with a "sense" to be on the lookout for unforeseen phenomena. Provision for sensing the unexpected can be awareness-programmed by Earth-bound designers of space experiments: for example, the instance of a space sensor to switch to a supernova should one be noted within the observing sphere of the sensor. Specialists are aware of similar "surprise" situations in other fields of research. Such information could be invaluable as compared with just a few more routine measurements in a long chain.

3. *Multidisciplinary Collaboration in Design of Experiments*. Although there are a multitude of specialties among scientific researchers, there are many common threads that are interwoven throughout the total fabric of science. The value of intermingling the scientific disciplines by way of periodic symposia, the technical literature, and teaching at the university level, all bring common information and "ideas" to the scientific community. The computer-assisted collaboratory effort, as outlined by the NRC, can create a manifold increase in such interest and cooperation.

Workstation Clusters

A workstation cluster may be defined as a group of workstations or high-performance microprocessor systems linked together in a network such that the user, in essence, works with a single source of computer power. To a degree, this configuration can be a substitute for a single high-performance supercomputer. As of the mid-1990s, some users had found the workstation cluster ample for their needs. B. Bazbee (Scientific Computing Division, NCAR) cites the following advantages of the cluster approach:

1. Cost-effective alternative to mainframe systems.
2. Cost-effective alternative to providing a workstation to each scientist and engineer in an organization.
3. An approach to utilizing otherwise unused cycles on personal workstations.
4. Providing a loosely-coupled parallel capability.

An example of the cluster approach is provided by the NCAR, which interconnects a cluster of four IBM RS/6000 Model 550s with serial optical links and a Network Systems PB290 router. Early experience indicates that this cluster, by means of parallel processing, can support real-time weather forecasting at a level comparable with one processor of a Cray Y-MP. See also **Weather Technology**.

Packaging

As early as the 1960s, the Control Data 6600 computer used three-dimensional discrete transistors and resistor logic modules. Wiring was tuned by lengths and Freon cooling was used. These design innovations reduced size requirements as well as improved performance. The trend to use small transistors and resistors has continued. Cray Research pioneered the use of early integrated circuits. To further increase performance, designers found ways to reduce the interconnect distances. As of the early 1990s, computer designers are turning to Massively Parallel Systems (MPSs) that use standard packaged logic and memory chips, all contributing to logic size reminiscent of the earlier supercomputers. The resulting large interconnect distances affect cost and performance. Too detailed to describe here, L.M. Thorndyke (DataMax) and J.P. Riganati (David Sarnoff Research Center) summarize ongoing development of the MPS design philosophy. (See reference listed.)

Numerous other articles in this encyclopedia describe computers and their applications. Pertaining to the future, see also **Molecular and Supermolecular Electronics**.

DIGITAL IMAGING. See **Photography and Imagery**.

DIGITALIS *(Digitalis purpurea; Foxglove, Scrophulariaceae)*. The foxglove is a biennial often grown as an ornamental plant. The first year of growth produces only the long basal leaves, while in the second year the erect leafy stem 2–5 feet (0.6–1.5 meters) tall is developed. The flowers are borne in a raceme, which, through the bending of the peduncles or individual flower stalks, becomes one-sided. The purple flowers have a five-parted calyx, a tubular bell-shaped corolla obscurely five-lobed, five stamens and a single pistil. They are pollinated mainly by bees. The fruit is a two-celled capsule.

The drug digitalis is prepared mostly from leaves of the second year's growth. These are rather coarse ovate leaves covered with glandular hairs. Decoctions of the leaves have been used in Europe for many years. See also **Arrhythmias (Cardiac)**; and **Congestive Heart Failure (CHF)**.

Digitalis is a valued drug in medicine and is used in certain kinds of heart disease. The chief effects it has on the heart are the regulation of its rate, rhythm, tone, contraction, and conduction of impulses.

As a crop plant, digitalis is grown in England, Germany, and in the United States, especially in Michigan. Propagation is by seeds, which are sown under glass and later transplanted.

DIGITAL MULTIPLEXER. A device that permits sharing a common information path between multiple groups of input or output digital signals. For example, a digital multiplexer can be used to transfer information between the central processing unit (CPU) of a computer and any one of several digital input or output devices. A form of digital multiplexer for use in reading information of groups of contact points is shown in Fig. 1. To read the status of contacts in group A, a positive signal is transmitted on the group A select line. Should the contact be closed, the positive signal appears on the associated bit line. Bit lines are sampled during the period when the select line is active. The status of the group of contacts is stored in computer memory. Upon completion of the operation, the signal on the select line is removed. When it is desired to read group B, a positive signal is placed on the group B select line and the status of the contacts in group B is placed on the associated bit lines. Diodes in series with the contacts are needed to prevent back circuits; the number of groups that can share the same input bit lines is a function of the back resistance of the diode.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

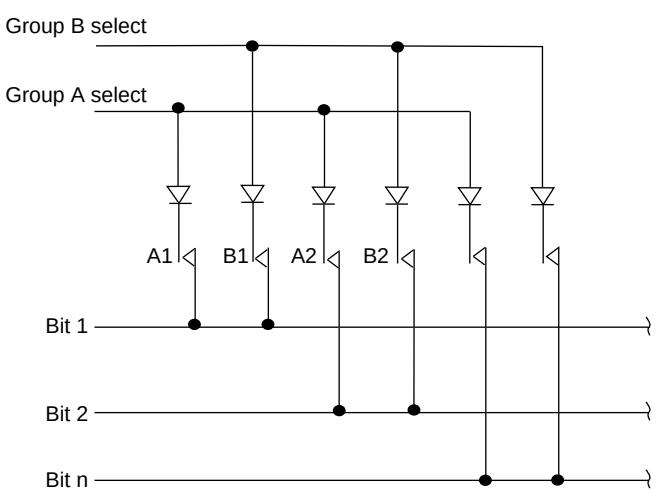

Fig. 1. Digital multiplexer.

DIGITAL NETWORK. See **Telephony (Telecommunications)**.

DIGITAL OUTPUT. The digital-output information of a computer may be a contact-operate signal or a voltage-level signal. Under the control of the computer program, the digital information is transferred from the central processing unit to a digital-output register. The output of the register may be connected directly to the digital-output signal lines to provide the voltage-level signal. To provide the contact-operate signals, the output of the register is connected to a driver circuit connected to the digital output signal lines. When a register position is turned on, the drive circuit provides the current, which actuates an external device, such as a relay. The information remains in the register until another computer command to the same group of digital-output points is executed, or the register may be reset as the result of a signal from the external device or after a fixed time interval has elapsed.

DIGITAL PROCESSING AND INFORMATION TECHNOLOGY IN IMAGING. During the past decade the practice of radiology has experienced drastic changes in the methods of service employed to provide interpretation expertise to the medical community. The advent of new acquisition devices, new image formats, interpretation formats and dictation technology has transformed the way in which radiologists practice. Traditionally, energies have been focused towards the development of new tools predominantly to image the human body with attempts to refine diagnostic methods. However, radiological practice has recently seen the development of methods and technologies that serve to improve aspects of radiology outside the diagnostic realm. These developments have promised to provide better service and ultimately are intended to improve patient care. The growth in this area has led to the development and installation of technologies such as picture archiving and communication systems (PACS) and teleradiology. See also **Imaging (Medical): An Overview**.

The legacy system in many departments of radiology for delivery of radiological services hinges on the use of radiographic film. The workflow of imaging studies thus traditionally commences with a manually completed and scheduled request sent by a referring physician. Once the study has been scheduled into a queue, the patient is imaged and film-based images are printed. This film is subsequently correlated with prior imaging studies the patient has had performed and these are arranged for interpretation and dictation. Once reviewed by a radiologist, a report is dictated and transcribed by a transcription service ultimately sent to referring physicians. Several forms of distribution exist in various departments for provision of these reports to referring physicians, ranging from telephone to fax to fully developed hospital information systems (HISs).

Attempts are now in progress to automate each aspect of the imaging process, with PACS automating the processes within the radiology department from image delivery to storage, and to billing where appropriate. These processes are slowly being integrated as departments make the transition to fully digital enterprises.

Activity within the digital department begins with online order entry via distributed terminals or worldwide web-based entry protocols. Upon entry, the order is scheduled within the radiology information system (RIS) and concurrently this information is passed to a broker within the PACS to ensure the timely retrieval of prior studies for comparison. Once the patient has been imaged, the acquired images become available to the enterprise. The distribution of images to the enterprise is routinely accomplished through various means including, but not inclusive of, the Internet.

Image Acquisition

Nearly 60% of the RVUs (relative value unit) of imaging today comes from cross-sectional digital modalities. These modalities include computed tomography (CT), magnetic resonance imaging (MRI) and ultrasonography. The remaining imaging services include radiography, from conventional to interventional radiology and mammography. For true integration into the digital department, it is necessary for devices that produce images to be capable of producing digital data in a conventional format. CT, MRI and ultrasonographic acquisition devices produce digital output, with most current systems offering digital imaging and communications in medicine (DICOM) protocols for communication. Many older systems that were installed before definition of the DICOM standard often do not offer DICOM connectivity for which there are third-party add-on devices that perform conversion. As a large portion of imaging volume is centered around conventional radiography, the integration of plain film radiography into a digital architecture is paramount. Currently, radiographic devices are available in two formats: analogue (often termed conventional) and digital (often referred to as computed radiography). The

distinction between these imaging systems becomes important when determining whether the modality is capable of producing the necessary digital data for integration into the digital department. Emerging on to the market are mammographic devices that produce digital output, but currently their costs are significantly higher than that of their analogue counterparts. See also **Computed Tomography**; **Magnetic Resonance Imaging (MRI)**; and **Ultrasound**.

Image Archiving

Almost 90% of healthcare information is still stored on paper. However, within the practice of radiology, film is still the predominant storage medium. Current systems process image data which are subsequently printed on film, stored in film jackets and housed in film libraries. This system is plagued with loss of data, lengthy retrieval times, and high costs associated with physical storage space. With the advent of PACS and digital imaging, the concept of digital storage for radiology applications has emerged and is quickly becoming commonplace. At the heart of a PACS is the archive. The archive's function is to store, identify and protect image data. In contradistinction to conventional film libraries, the digital archive is able to perform these tasks with decreased costs, more robust security and zero loss of data.

Basic definitions of storage of data include an understanding that one bit is a single block of data; it can have a value of 1 or 0. One byte is made up of eight bits; a kilobyte (kb) is made up of 1000 bytes and a megabyte (Mb) is a million bytes. A gigabyte (Gb) is 1,000 megabytes, a terabyte (Tb) 1,000 gigabytes, and finally a petabyte (Pb) is 1,000 terabytes. Today's average radiology examination has a data size of approximately 20 Mb. Thus, average departments performing 100,000 imaging studies per year require 10–20 Gb online storage and 2–4 Tb of nearline storage or long-term storage. There are various archiving levels required in a filmless environment, from immediate access memory to nearline storage to deep archive storage. The options for solution at each of these levels of archive are described below.

Short Term

Random Access Memory. Random access memory (RAM), as found in the desktop PC, is a data storage medium for which the speed of access to the data is unaffected by the order of access to data in any location. The most common form of RAM in use today is built from semiconductor integrated circuits. RAM can be configured in sizes of up to 1 Gb and access to data can occur in the nanosecond range.

Magnetic Disk. A hard drive in a desktop PC is a flat rotating disk covered on one or both sides with magnetizable material. In order to store information, small areas or "zones" on a magnetic disk are magnetized. Data are read and written by a head that is positioned at various parts of the disk by a spinning mechanism. Hard disks have an access time in the 20–30 ms range, and can store up to 20 Gb of data.

Medium Short Term

Redundant Array of Inexpensive Disks. A redundant array of inexpensive disks (RAID) consists of hard disk drives linked together in series. RAIDs increase data protection and availability, increase total storage capacity, and provide performance flexibility. Overall performance can be improved by spreading data and performing operations in parallel, allowing multiple drives to be working on a single input or output request. RAID configurations can store up to 1 Tb of data and have access times similar to those of magnetic spinning disks or hard drives.

Long Term

Compact Disk Recordable. Compact disk recordable (CDR) is a user-recordable compact disk, a format that is routinely available both in the retail industry and now at home. CDR technology creates a CD-ROM disk that provides 650 Mb of storage per disk. CD-ROM jukeboxes and library systems provide fast, high-volume, permanent storage capabilities. Conventional CD-ROM jukeboxes can house from 200 Gb to 1 Tb of data depending on the number of platters and disk changers, with average access times for random queries incorporating the robotic arm change time in the seconds range.

Digital Versatile Disk. Digital versatile disk (DVD) physically comes in two formats: a two-layer single- or double-sided disk with a capacity of 8.5 or 17 Gb, or a single-layer single- or double-sided disk with a capacity 4.7 or 9.4 Gb. DVD drives are backwards compatible with the current CD-ROM format, so single drives can meet both requirements. Average access times are similar to those of the CDR format.

Optical Disk. Magneto-optical disks are $5\frac{1}{4}$ inches in diameter and are coated with a material with special properties. Optical disks come in two varieties, "write once read many" (WORM) and "magneto optical" (MO), with the MO disks being rewritable many times. Conventionally, optical disks can hold up to 2.6 Gb of data and, when linked into a jukebox with a conventional number of platters, together can hold 1.3 Tb of data.

Digital Linear Tape. Digital linear tape (DLT) employs magnetic tape drives as a storage medium. DLT drives use a tape cartridge, 4.1 inches square and 1 inch high, which holds this half-inch metal-particle magnetic tape. DLTs are half an inch wide and the cartridges come in several capacities, ranging from 20 Gb to over 40 Gb.

Image Transmission. The ultimate benefit of digital data is the ability to transport data to multiple locations in real-time concurrently. The transport of data through a radiology department and the enterprise allows availability of images to all points connected to the network almost simultaneously. The advent of the production of digital (usually DICOM) data has drastically simplified the processing and transmission of data by defining standard routine protocols and routines that each device can comprehend. This convention is utilized from routine tasks including digital transmission to produce output on a film printer for subsequent hard-copy interpretation to storage in a central archive.

The advantages of specific network technologies such as T1, T3, Integrated Services Digital Network (ISDN) and Asynchronous Digital Subscriber Line (ADSL) are varied. There are nuances in the technologies that result in different levels of performance, but the common factor remains that each of the listed technologies is capable of transmitting with the transmission control protocol/Internet protocol (TCP/IP). This protocol is the standard communications protocol used throughout the Internet and hence ensures stability and vendor support. The use of these protocol technologies also permits the capability of extending the department or hospital local area network to remote sites through a wide-area network.

Remote transmission of images can be performed with digital data and is performed for several reasons. Primarily, the distribution of images to a healthcare enterprise is needed for patient care and patient education. However, within the radiology department, remote image access can serve the purposes of teleradiology, on-call services and online consultation. The remote transmission of images can be performed via proprietary or public technology concurrently with standard modems or via the Internet.

Image Interpretation

A primary interpretation workstation is a computer system used to interpret images being generated within the digital department. Each of these workstations is connected to a central PACS and indirectly to remote imaging centers. These connections are performed over network lines and to remote centers via Internet or intranet. The existence of these connections ensures the ability for the radiology enterprise to be able to deliver images from any location for ubiquitous interpretation. The typical scenario in the digital department employs the use of a centralized RIS for both scheduling and reporting purposes. The addition of linking technologies allows the pertinent information on the RIS to be available to the remainder of the enterprise via a HIS interface. The current workstation configurations use the Unix operating system and custom-designed software, but there is a shift in the industry to move towards more common platforms and open source software packages. This software is geared toward image interpretation, providing the radiologist with multiple tools for image manipulation, management and creation. Current offerings include many iterations of worklist paradigms that provide case review lists based on indicators of study status (from new to reported). This allows the radiologist constantly to monitor the flow of studies during a workday. In order to provide services to the remainder of the enterprise, web-based solutions are commonly employed for distribution to the other locations within the hospital outside the radiology department. See also **Image Analysis Workstations**.

Teleradiology

Perspective. Teleradiology is one of the most developed forms of telemedicine, and can be defined as the "delivery of health care and sharing of medical expertise using a telecommunications system." Telemedicine does not define the distance over which medical information is shared,

although it is typically thought to be outside any local area. From a purely historical perspective, the telephone remains the standard method for communicating medical information. Teleradiology itself became an entity in the1960s when Dr Kenneth T. Bird of the Massachusetts General Hospital used an interactive television linked via a direct microwave link between Logan Airport in Boston and the hospital approximately 3 miles away. Owing to large strides in improvement in technology, teleradiology is now rarely practiced using interactive television or video. Since the 1960s, the field of telemedicine and teleradiology showed little advance outside military applications, and it was not until early in the 1990s that realistic bandwidths became available for the transmission of large data files. As bandwidth and compression algorithms became more commonplace, the mid 1990s experienced the explosion of the implementation of teleradiology in the United States.

Technology. For a radiological image to be transmitted over telecommunications systems, the image must be converted to a digital format. Once digitized, there are several factors that require balancing for teleradiology to become an effective method. Typically, the file sizes for digital images are very large, ranging from hundreds of kilobytes to 40–50 Mb. These large files can take many hours to transmit across standard phone lines. In this modern era of medicine, the complicating factor for teleradiology practices are the increasing number of studies performed on patients in order to evaluate a single disease. This leads directly to a large increase in the volume of information that needs to be transmitted. Of importance is the realization that a single image from a CT study may not take very long to send from one site to another, but a single slice is of limited utility to the radiologist interpreting the patient's studies. Hence, the use of conventional network transmission methods becomes expensive and impractical; fortunately, the 1990s witnessed a revolution in the use of information technology, with rapidly increasing availability of bandwidth. However, this incredible change has come with a cost. There is a direct relationship between the amounts of bandwidth and cost, but with this increased availability of bandwidth comes the possibility of sending extremely large file sizes many thousands of miles in seconds. In summary, for teleradiology to be cost effective, some method is required to reduce the file sizes of digitized images, without compromising image quality. The solution to this problem has been solved, especially for large medical image files, as well as in the entertainment industry, by compression algorithms. These algorithms can compress images 20–30 times their original size and make transmission fast and inexpensive. Once received at the interpretation site, the images can be decompressed and either sent to dedicated workstations or integrated into a local area network (LAN) and PACS. With these technologies, teleradiology can be a feasible addition to a radiology practice and help to serve both underserved areas as well as locations where subspecialty consultative services are not readily available.

Conclusions

The creation of a filmless department and protocols for digital image management have become a reality. The creation and introduction of technologies such as PACS, RIS and the HIS have contributed directly to the creation of services such as telemedicine and teleradiology. The continued automation of processes within radiology serves to improve the efficiency of radiologist's workflow and directly lead to improved efficiency for patient care.

PACS. Picture archiving and communication system. This is the term applied to the infrastructure that provides filmless medical imaging to a radiology department. The components of a PACS include the image acquisition devices, the image storage devices and the image display devices, as well as the networks and add-on components that provide this connectivity.

RIS. Radiology information system. This is a computer system (in the past, usually mainframe types; more recently, powerful PCs) that handles workflow components of a radiology practice including scheduling, billing and reporting.

HIS. Hospital information system. This is a computer system (usually mainframe types) that handles the flow of information pertaining to patient data throughout a hospital or hospital network system. This often contains laboratory data, operative reports, patient demographics and, more recently, has begun to incorporate radiology data through a HIS–radiology information system (RIS) interface.

DIGITAL-TO-ANALOG CONVERTER. Abbreviated D/A converter or DAC. A device for generating an analog voltage or current which is proportional to the value of a digital-input word. Frequently, in systems under the control of a digital computer, analog signals must be generated to cause actuation of analog devices. The latter include positioning mechanisms, such as valve positioners, graphic displays, such as X-Y recorders, oscilloscope displays, and strip-chart recorders. D/A converters also are used apart from computers to provide voltages proportional to the settings of input switches.

The majority of D/A converters consist of a D/A converter decoder network, an analog switch for each digital-input bit, a buffer amplifier, and the necessary control logic in a configuration along the lines of Fig. 1. The decoder network is an electronically controllable attenuation network whose attenuation factor is proportional to the position of the input switches. The analog switches, under control of the logic, either connect the reference source to the decoder-network input terminal or ground the terminal. This results in an output voltage that is proportional to the setting of the switches.

The control logic provides digital storage of the input-data word and control of the switch position. Additionally, it may provide decoding of addresses and the digital multiplexing of digital data to one of several D/A converters included in the subsystem. Impedance buffering and current-driving capability are provided by the buffer amplifier. Generally, this is required because the output impedance of the decoder network is relatively

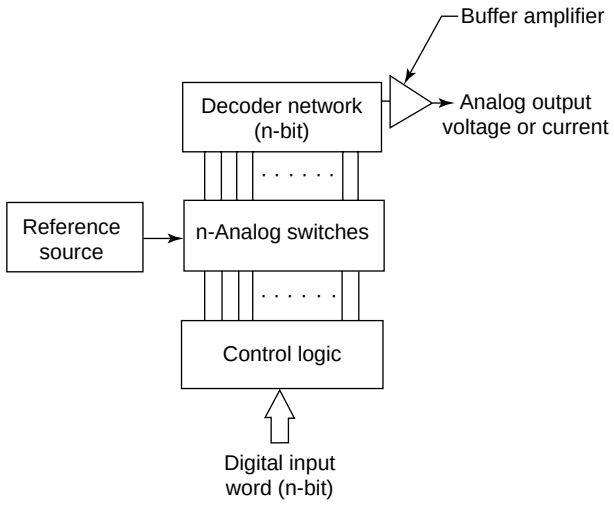

Fig. 1. Representative digital-to-analog converter.

high. Driving loads directly from the decoder network can result in loading errors that may be intolerable in a high-accuracy system.

Another D/A converter configuration is shown in Fig. 2. This is comprised of control logic, a decoder network, a reference source, and an operational amplifier.

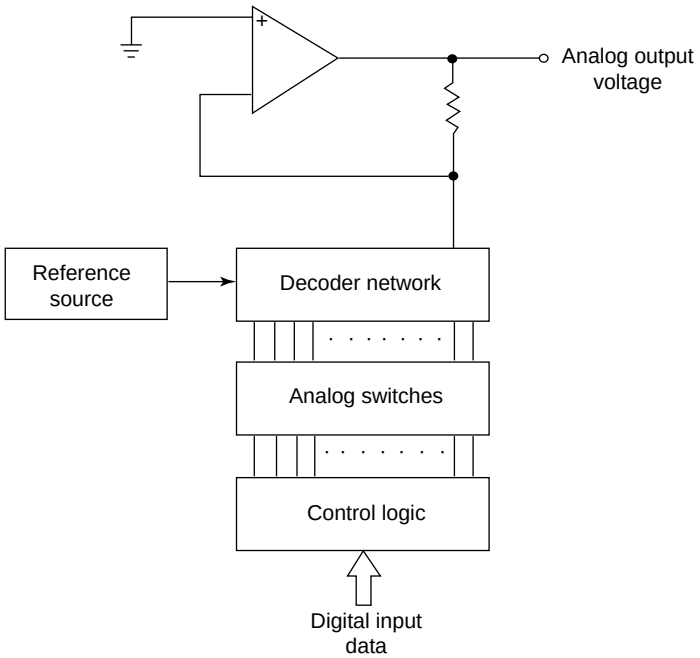

Fig. 2. Operational-amplifier type digital-to-analog converter.

Decoding Networks

The two major decoder networks are shown in Figs. 3 and 4. Although the ladder networks shown are n-bit decoders, other codes can be realized by appropriate modifications. As an example, in a weighted-resistor binary-coded-decimal decoder, the configuration is identical, but the resistors are R, 2R, 4R, ...; in the ladder decoder, the resistors are R and 2R, but an attenuation network providing an attenuation factor of 0.8 is inserted between each 3-bit section of the ladder decoder to provide the binary-coded-decimal output.

The weighted-resistor network of Fig. 3 is used with a voltage-reference source. Each of the terminals $1, 2, \ldots, n$ either is connected to the reference voltage V_r, or it is grounded. If the kth node is connected to V_r and the other $(n-1)$ nodes are grounded, the output voltage V_0 is

$$V_0 = \frac{V_r}{1 + G_L/2G} \sum_{k=1}^{n} A_k 2^{-k} \quad A_k = 1, 0$$

where A_k is an index which is 1 when $k - n$ terminal is connected to the voltage source and 0 when it is grounded. If the conductance $G_L = G$, the

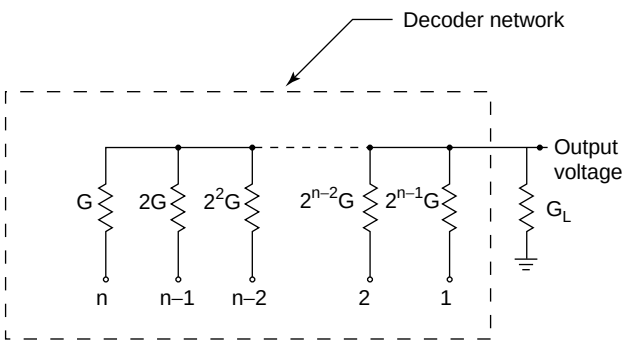

Fig. 3. Weighted-resistor decoder network.

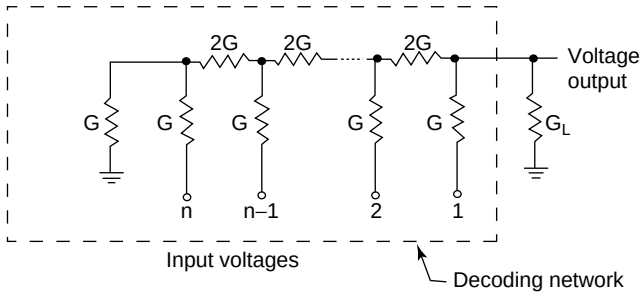

Fig. 4. Ladder decoder network of the R = 2R type.

expression reduces to

$$V_0 = \frac{V_r}{2^n - 1 + G_L/G} \sum_{k=1}^{n} A_k 2^{n-k} \quad A_k = 1, 0$$

which shows that the output voltage is binary and is determined by the conditions at the input terminals. The input conductance at the kth terminal when G_L is assumed equal to G is

$$G_{\text{in}} = 2^{n-k}(1 - 2^{-k})G$$

and the output conductance of the network is $2^n G$, a constant. Although this network is designed for use with a voltage-reference source, a similar network can be designed for use with current-reference sources.

The resistor network of Fig. 4 is commonly known as the R-2R ladder network. Either a reference voltage is connected to the kth terminal, or the terminal is grounded. The expression for the output voltage is

$$V_0 = V_r \sum_{k=1}^{n} A_k 2^{-k} \quad A_k = 1, 0$$

where $A_k = 1$ when the kth terminal is connected to the voltage V_r and 0 if the terminal is grounded. If the load resistance G_L is made equal to 0, the expression becomes

$$V_0 = V_r \sum_{k=1}^{n} A_k 2^{-k} \quad A_k = 1, 0$$

which shows the binary contribution of each input. The output conductance is constant and is equal to $2G$ if $G_L = 0$. The input resistance is also constant and is equal to $2G/3$. A similar network can be used for current sources.

The weighted-resistor network uses a minimum number of resistances. The ratio of the largest to the smallest resistor is 2^{n-1} (or 512 for $n = 10$) as compared with only 2 for the ladder network. The type of resistor used in the network depends primarily on performance limitations and cost. Discrete wire-wound resistors are often used for high-precision networks which have a very low temperature coefficient. Film-type resistors can be used where the temperature-coefficient and precision requirements are less.

THOMAS J. HARRISON
International Business Machines Corporation, Boca Raton, FL

DIGITATE DRAINAGE. The term applied to the fingerlike pattern of stream valleys. Such a stream pattern usually develops only when the underlying formations are relatively horizontal or if folded, faulted, or metamorphosed, are relatively of equal hardness and solubility.

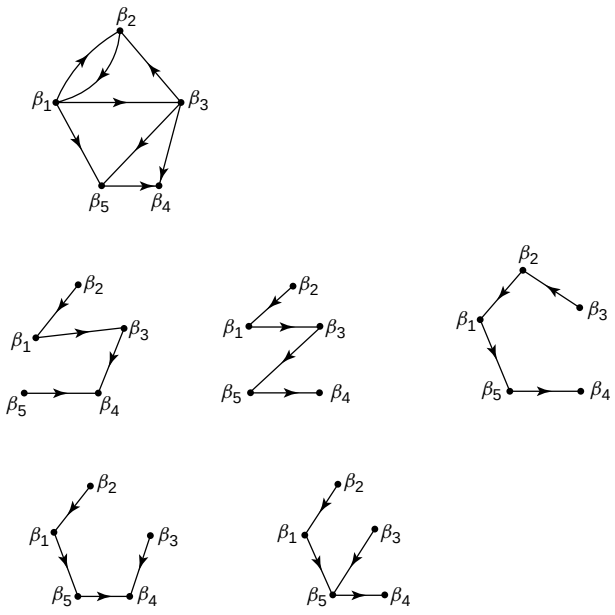
DIGRAPH. A digraph D is a finite set of vertices $\beta_1, \beta_2, \ldots, \beta_v$, together with certain directed lines $\boldsymbol{\beta_1\beta_2}$ (from vertex β_1 to β_2). The possibility that both $\boldsymbol{\beta_1\beta_2}$ and $\boldsymbol{\beta_2\beta_1}$ are lines of the digraph is not excluded. Thus an oriented graph is a digraph but not conversely.

The adjacency matrix (see also **Matrix (Adjacency)**) $A = (a_{ij})$ of a digraph D is defined as follows: $a_{ij} = +1$ if line $\beta_i\beta_j$ is in D and $a_{ij} = 0$ otherwise. It is important to note that A is not necessarily symmetric $(a_{ij} = a_{ji})$ as is the case for the adjacency matrix of a nonoriented graph. A is square and of order v, the number of vertices.

A tree T of D with sink β (a vertex) has the following characteristics:

(a) T is a subgraph of D that contains all the vertices of D;
(b) in T there is a directed path leading to β from every other vertex in D;
(c) every vertex other than β is the initial vertex (see **Vertex**) of exactly one directed line in T;
(d) there is no directed line in T for which β is the initial vertex.

An example of a digraph and its five trees is given in Fig. 1.



$$M = \begin{vmatrix} 3 & -1 & -1 & 0 & -1 \\ -1 & 1 & 0 & 0 & 0 \\ 0 & -1 & 3 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 1 \end{vmatrix}$$

Fig. 1. Digraph and five trees.

The degree matrix B for D is defined to be that diagonal matrix of order v which is such that the difference $M = B - A$ has every row sum to zero. The matrix tree theorem for digraphs states that the co-factors of the elements in the ith row of M are all equal and each of them gives the number of trees of D with sink β_i. The matrix M associated with the digraph D of the illustrative example above also appears in the figure.

DIHEDRAL ANGLE. See **Angle**.

DIKE (or Dyke). A tabular, intrusive mass of igneous rock that cuts across other igneous rock bodies, such as batholiths; or cuts across the bedding (stratification) of lavas or sedimentary formations. Not to be confused, in the chemical and mineralogical sense, with veins; or, in the structural sense, with sills.

DILATANCY. The property of certain colloidal solutions of becoming solid, or setting, under pressure. Also known as "inverse plasticity" since there is an increase in the resistance to deformation with increase in the rate of shear.

DILATATION. The increase of volume per unit volume of a continuous material.

DILATION. The fractional increment in volume caused by a deformation or phase change.

DILATION NUMBER. Ratio of the volume of a liquid to the volume of a solid of the same composition at the same temperature.

DILATOMETER. 1. An instrument used to measure small increments in the volume of liquids, as a solid phase separates.

2. An instrument for measuring very small length changes in a solid metal specimen such as occur during thermal expansion or phase transformations.

DILUENT. 1. An ingredient used to reduce the concentration of an active material to achieve a desirable and beneficial effect. Examples are combination of diatomaceous earth with nitroglycerin to form the much less shock-sensitive dynamite; addition of sand to cement mixes to improve workability with no serious loss of strength; addition of an organic liquid having no solvent power to a paint or lacquer to reduce viscosity and achieve suitable application properties.

2. Low-gravity materials used primarily to reduce cost, e.g., blown asphalt, wood floc, etc., in rubber and plastic mixes. In this sense, there is no clear distinction between a diluent and an extender.

3. An ingredient of rocket fuels, such as helium, hydrazine, or hydrogen.

DILUVIUM. Derived from the Latin *diluere*, to wash apart, through *diluvialis*, flood. A relatively obsolete geologic term formerly applied to certain water-laid deposits within or bordering the glaciation regions of Europe and North America. Most of the sediments which were previously thought to have been the result of the "flood," and which are now known to be stratified drift, were called diluvium. In Germany, the term corresponds to Pleistocene.

DIMENSIONAL ANALYSIS. A method of determining possible relationships between meteorological variables based on their dimensions. A systematic method called Buckingham Pi theory can be used to find such relationships. The results are often expressed as dimensionless groups, called Pi groups. While Buckingham Pi theory helps to identify the appropriate dimensionless groups, it cannot indicate the relationships between the groups. Such relationships must be found empirically, based on field or laboratory measurements of the dimensionless groups. When the empirical data are plotted on graphs of one dimensionless group versus another, often data from many disparate meteorological conditions will result in one common curve, yielding a similarity relationship that may be universal. Dimensional analysis has been used extensively and successfully in studies of the atmospheric boundary layer, where turbulence precludes other more precise descriptions of the flow because exact solutions of the equations of motion are impossible to find due to the closure problem.
